ORIGINAL ARTICLES.

DIPHTHERIA; ITS BACTERIAL DIAGNOSIS AND TREATMENT WITH THE ANTITOXIN.[1]

BY HENRY W. BETTMANN, M.D.,
OF CINCINNATI, OHIO;
CURATOR AND MICROSCOPIST, CINCINNATI GENERAL HOSPITAL.

IN 1884 Loeffler announced the cause of diphtheria, but the medical world was little interested. Five years later Roux declared that the bacterial diagnosis of suspected cases was of the greatest importance, and Baginsky added further proof, and still the medical world heeded little. In 1894 Roux and Behring announced independently that they had discovered a cure for diphtheria, and in six months the medical world is aflame.

The scientific structure is complete: the etiology first, the bacterial diagnosis second, the prophylaxis and cure the capping-stones. The task before the medical profession is to see if the structure can stand. If it stands, it is the highest achievement of the new medical era, and a glorious and memorable tribute to scientific medicine.

I shall say nothing about the etiologic relation between the Loeffler bacillus and diphtheria. In the minds of all except the ultra-skeptical, the cause of the vast majority of cases of Bretonneau's diphtheria is the Loeffler bacillus; this fact was incontrovertibly demonstrated years ago, and need no longer form the basis of discussion. The questions that concern us to-night are far more practical and more important to us as physicians. They may be enumerated as follows:

1. What clinical significance has the bacterial investigation of throat-exudates?

2. Can diphtheria be cured by the antitoxin?

3. Can diphtheria be prevented by the antitoxin?

4. Is the antitoxin a specific remedy for diphtheria in the sense advocated by Behring, Aronson, and Roux?

1. *The Clinical Significance of Bacterial Investigation of Throat-exudates.* My conclusions are based on the bacterial investigations of 122 throat-cases. These studies were made in the laboratory of the Cincinnati Hospital by Dr. A. H. Freiberg and myself, with the generous assistance of Dr. Charles H. Castle. We are also indebted to the assistance of Superintendent Hendley, who first suggested the investigation. Our methods were copied from those of the New York City Board of Health, and our way of distributing, collecting, and examining tubes was modelled after that of New York. Altogether we examined about 160 inoculated tubes. A majority of the local profession did not avail themselves of the opportunity for diagnosis that was offered. On the other hand, a large number realized the value of the bacterial examination and lent us their support and their interest. The vast majority of the tubes examined were sent to us in January, February, and March of this year.

In all cases we used Loeffler's serum for diagnostic purposes. This is by far the best medium with which to demonstrate the presence of the Loeffler bacillus. Investigators who use glycerin-agar, peptone-agar, or even plain blood-serum cannot expect reliable results.[1] As a rule, we were able to make a diagnosis after the tubes had remained in the incubator from twelve to sixteen hours; and if the inoculation was at all successful, twenty-four hours sufficed in all cases. With some experience it is possible to distinguish diphtheria-colonies from cocci-colonies macroscopically, diphtheria-colonies of sixteen hours' duration looking gray and small as compared with the larger and whiter cocci-colonies; of course, it is best in all cases to resort to microscopic examination with alkaline methylene-blue. Early in January we were puzzled occasionally by the appearance in the cultures of short, thick bacilli, and very long, slender, evenly staining ones. We soon found out, however, that these colonies developed in imperfectly sterilized tubes, and later ruled out all doubt by sterilizing the serum more perfectly. After this we were never seriously puzzled to know whether a tube contained Loeffler bacilli or not. After the statistical report of the New York Board of Health, covering 5611 cases, it might seem superfluous for us to report our series of 122. Yet even so small a series is full of interest and instruction.

The Loeffler bacillus was present in forty-seven cases; of these, eight, or 17 per cent., died. The bacillus was absent from seventy-five cases; of these, three (4 per cent.) died. In one of these fatal cases the examination was made after the disease had existed two

[1] A paper read before the Cincinnati Academy of Medicine, June 3, 1895.

Compare also the defective results obtained by Vierordt (Deutsche med. Woch., 1895, No. 11, p. 169), by use of plate-cultures of glycerin-agar.

weeks, and proved negative; in another, on the eighth day, two days before death, and it was also negative. Everyone familiar with the subject knows, and the New York report has sufficiently emphasized the fact, that examinations made quite late in the disease are not reliable, and we may properly exclude these two last-mentioned cases from our consideration. Thus, out of seventy-three cases in which no Loeffler bacilli were found under proper conditions of examination, only one proved fatal, or nearly 1½ per cent., while 17 per cent. of those died in whom the Loeffler bacillus was found. This teaches one important lesson, viz., the presence of the Loeffler bacillus in the throat adds very seriously to the gravity of our prognosis.

But mortality is not the only test of severity. A few weeks ago I sent postal cards to the physicians who had had cases examined, asking for clinical data, laying special stress upon the duration of the disease, the presence of alarming symptoms, the occurrence of sequelæ and complications, and the condition of the heart. I received complete data concerning forty-one cases, in which the Loeffler bacillus had been found; in eighteen of these (just 40 per cent.) the physicians reported the patients as *dangerously* sick, in many cases from weakness of the heart; of the non-diphtheric cases, aside from the three that died, *only one patient* was reported as having been in danger, and that one from laryngitis; *i. e.*, seventy-one out of seventy-five cases from which the Loeffler bacillus was absent ran a mild course without arousing any alarm.

Can anything be more convincing than that the bacillary sore-throat is a very different disease from the non-bacillary sore-throat? So much for gross figures. I think, however, that examination into the details of several series of cases will prove still more striking and show still more forcibly the value of bacterial diagnosis.

On January 5th a tube was sent with the diagnosis of tonsillitis. The physician in charge said that there was no suspicion of diphtheria, and the patient was not isolated. Two days later the child's brother contracted an angina. Bacterial examination of the first case revealed the presence of many cocci and few Loeffler bacilli; the second throat contained almost a pure culture of Loeffler bacilli. Both children were markedly prostrated, out of all proportion to the apparent throat-lesion; the first child was weak for a month after recovery; the second child was in great danger from heart-failure for a week, and suffered later from paralysis of the pharyngeal and ocular muscles.

On February 14th a tube was sent with the diagnosis of severe tonsillitis. Examination revealed almost a pure culture of Loeffler bacilli. The case ran a very mild and favorable course for four days; on the fifth the patient, sixteen years old, died very suddenly from heart-failure.

In January a tube was sent with the diagnosis of non-diphtheric croup. No membranes were visible in the throat, and the temperature was normal. Intubation was performed. Bacterial examination revealed the Loeffler bacillus; stenosis returned, tracheotomy was performed, large tough membranes were found occluding the trachea, and the child died on the ninth day, after extension of the membrane to the lungs.

In March a tube was sent, and Loeffler bacilli were found in abundance. The first physician in attendance had diagnosticated catarrhal laryngitis, and had let the case run on from bad to worse for several days. He was then discharged. The second physician immediately had the case examined microscopically, and intubation was performed, but death followed after sixteen hours.

In all of these cases early bacterial examination would have thrown much light on the diagnosis and prognosis, and lives might have been saved. Other similar cases might be cited, but those detailed are sufficiently striking to show the great value to the clinician of bacterial investigation.

A few words in regard to the fatal cases in which no Loeffler bacilli were found. One was in a child, fourteen months old, that suffered from purulent coryza for two weeks, laryngeal stenosis and profound sepsis being present on its admission to the hospital. Only cocci were found after a minute examination. The antitoxin was used, and the child revived considerably. Cultures were made at intervals of two days, and no Loeffler bacilli were ever found. The child died seven days after admission to the hospital.

CASE No. II occurred in a family in which several members suffered from true Loeffler diphtheria. All the cases were malignant, and this one fatal, although no Loeffler bacilli were found. Only one culture was made, and I am inclined to believe that I must have made an imperfect examination, as Loeffler bacilli were found in other members of the same family.

CASE No. III was the one referred to. A six-months-old baby suffered with large extensive membranes in the throat; no culture was made until the eighth day, two days before the fatal issue. I am not informed as to whether the cause of death was croup or sepsis. There is no doubt that some cases of diphtheria occur in which Loeffler bacilli play no *rôle*. Fischer[1] reports a case of septic diphtheria in which cultures made daily for seven consecutive days failed to discover the Loeffler bacillus, and even a post-mortem culture revealed nothing but cocci. Fraenkel[2] admits also that there is such a thing as coccus-diphtheria, although its occurrence is quite rare. For the present we must simply shrug our

[1] N. Y. Med. Rec., April 6, 1895, p. 420.
[2] Loc. cit.

shoulders at these rare and unfortunate cases, and leave their explanation to further investigation.

I approach with some diffidence the subject of the therapeutic effects of the antitoxin. Veterans in medicine have tried it in a large series of cases, and have been reticent as regards the scientific value of their results. Rapidly, however, a large literature on the subject is accumulating, and it behooves us at least to keep in touch with the advanced thought. No one, I think, can follow what has been written on the subject during the past six months and regard it with indifference. Certainly no one can read the calm judicial testimony of medical experts in all parts of the world that classes of cases that formerly died do now recover, that a smaller percentage of cases die than formerly, and that severe cases now recover without need of operative interference, without wishing in his heart that such testimony is true. When men of world-wide reputation range themselves one after the other on the side of the new remedy we are compelled, with all our natural skepticism, to be encouraged. The names of Virchow, Escherich, Ganghofner, Ranke, Vierordt, all on one side, are strong testimony of themselves. In February of this year Foster[1] collected statistics of 2740 cases treated with antitoxin; of these 18.5 per cent. died; also of 4445 cases treated without antitoxin; of these 45 per cent. died.

I shall not load down your minds with bald statistics. Nothing is more tiresome or unprofitable. Since January of this year I have had occasion to observe closely seventeen cases of diphtheria. During February and March Dr. Forchheimer very generously placed his diphtheric patients at the City Hospital under my charge, and I am greatly indebted to him for the cases treated in that institution.

In January two brothers were admitted to the hospital suffering from a very severe form of diphtheria. The younger brother, four years old, had been sick eight days and had a very intense nephritis, with weak heart and complete anorexia. Many Loeffler bacilli were present; two days later they were absent from the throat. No antitoxin was used, owing to the condition of the kidneys and the advanced stage of the disease.[2] The nephritis grew worse daily, notwithstanding active treatment, and the child died twelve days after admission. The older brother, aged eight years, had contracted the disease three days before admission. At first he presented indications of only a moderately severe pharyngeal diphtheria and received tonic treatment. Soon, however, he developed a marked nephritis, like his brother, and five days after admission had severe symptoms of laryngeal stenosis; his temperature rose to 103.8°, and his condition became very critical. Ten c.cm. of the Roux antitoxin were injected in the interscapular space. During the next twenty-four hours the temperature fell steadily, the pulse-rate and frequency of respiration remained about the same, and the dyspnea was markedly moderated, recurring only for short intervals. The further course was favorable, the albuminuria lasted two weeks, Loeffler bacilli persisted only two days after the injection, and the boy made a slow but complete recovery. This, my first case, made a very favorable impression on me.

A week later a child aged fourteen months was brought to the hospital in an apparently moribund condition; the pulse was scarcely palpable; opisthotonos was marked, and the fetid odor from the throat scarcely endurable. The mother at first refused treatment, saying she did not wish the child uselessly tormented, and death seemed a question of only a few hours. We injected, however, 5 c.cm. of Behring's antitoxin, No. 2, and were much astonished to see in the course of twelve hours a remarkable change in the child's condition. It now sat up in bed and took nourishment greedily, but during the course of the day relapsed into its former condition. Injections of the antitoxin were repeated twice, both times causing a very marked and unmistakable change for the better. On the fourth day we were inclined to make a favorable prognosis; the heart, however, became very weak, the respirations rapid, fetid diarrhea set in, and the child died with high fever on the seventh day. Repeated examinations in this case failed to reveal Loeffler bacilli. Here was a case ending fatally, which, nevertheless, afforded to the few of us who witnessed it the greatest encouragement regarding the value of the antitoxin.

A few days later five children were placed under my charge at once. Two sisters, Mary and Gertrude E., aged respectively six and nine years, had extensive exudations with almost pure cultures of Loeffler bacilli, and yet the local and constitutional symptoms were so slight that no treatment was instituted, except rest in bed and light diet. Both cases developed albuminuria of moderate degree, which persisted sixteen days.

Three other sisters, aged respectively four months, four years, and six years, all had extensive exudations in which the Loeffler bacillus was demonstrated. One case ran so favorable a course that no antitoxin was used; on the second day the infant's temperature rose to 103 8° and the membranes extended. Five c.cm. of Behring's No. 2 were injected at 10 P.M., and the change for the better began in a few hours, and after that the temperature remained below 100° F., and no threatening symptoms recurred. The oldest sister received two injections of the antitoxin, each 5 c.cm., which seemed to affect the course of the disease very favorably. These children also had albuminuria lasting two weeks, the one in which no antitoxin had been used no less than the others.

I shall not detail all the cases treated. One child, aged ten years, received 10 c.cm. of the antitoxin for laryngeal obstruction present on admission, and

[1] Foster: THE MEDICAL NEWS, Philadelphia, Feb. 2, 1895.

[2] Neither of these conditions, however, is a contraindication against the use of antitoxin.

died four hours afterward from sudden increase of stenosis. All the other cases recovered, some with and some without the antitoxin. Altogether, nine cases received the antitoxin; two of these died, as already recited. Of the seventeen cases observed, three died, representing a mortality of 17.6 per cent.

The mortality in the city during January, February, and March was 26 per cent. I do not lay any stress on the results obtained by us in the hospital. The number of cases is too small to be convincing. All who saw the cases treated with the antitoxin felt sure that we had in our possession a wonderful remedy. This subjective feeling of trust in the value of the antitoxin is almost universal among those who have tried it in any number of cases, and speaks more in favor of the remedy than the published figures. I shall reserve for another occasion a critical estimate of the antitoxin-literature thus far published.

Of some things I am convinced:

1. That the antitoxin does undoubtedly affect favorably a large number of diphtheria-cases.

2. That it is the duty of physicians to use the antitoxin early in every case of severe diphtheria occurring in children.

3. That the mortality from diphtheria is destined to be largely diminished by prompt use of the antitoxin.

I cannot urge upon physicians too strongly to use the antitoxin *early* in their cases of diphtheria. The testimony is universal that the earlier the remedy is used the more certain is its curative effect. In Foster's table, of the 44 cases injected on the first day none died; of 106 cases injected on the second day 3 died. Later the mortality ranged from 10 per cent. to 40 per cent. In Ganghofner's table,[1] of 68 cases treated during the first three days 5 died; of 42 cases treated after the third day 10 died. In Kossel's well-known table, of 82 cases treated during the first four days only 2 died; of 35 cases treated after the fourth day 11 died. To wait for sepsis or laryngeal stenosis before using the antitoxin is folly. The chances of success are greater the sooner the remedy is used. All observers agree that when the antitoxin is used in pharyngeal diphtheria the larynx is not thereafter affected.

Bad effects from the antitoxin we did not see, although about twenty injections were made. I prefer the fleshy part of the thigh as the seat of injection. Pain was remarkably slight or wholly absent, and absorption took place in a very few minutes. One child had a slight erythema after the fifth day.

Can we prevent diphtheria with the antitoxin? The published reports of prophylactic injections are not very encouraging. As the antitoxin does not prevent the growth of the bacillus, it is hard to understand how it can prevent diphtheria. It has been noted that relapses after cure by the antitoxin are not infrequent; this itself is a strong argument against belief in any prophylactic virtue of the new medicine. As a matter of fact, diphtheria is not a highly contagious disease. Henoch says that in seventeen consecutive years only one attendant caught diphtheria in his diphtheria-pavilion. It is, therefore, a very difficult question to decide, especially as diphtheria occurs not infrequently in those prophylactically injected. Brewer[1] injected two children for the purpose of prophylaxis. One of them developed a membrane the next day, the other in six days after inoculation. Richter[2] made 72 preventive injections, and 7 of the persons were nevertheless affected. Sonnenburg[3] made 16 injections; diphtheria occurred in 2 of the cases. Hager[4] immunized 35 children and 3 took sick. Brunstein[5] immunized 28 cases and 1 took sick. Pearl[6] immunized 67 persons between the ages of four months and fifteen years; 13 contracted diphtheria and 2 died.

Summing up these reports we find that of 220 persons injected, 28 (12.7 per cent.) were nevertheless affected. This is certainly not a good showing. If one out of eight people had smallpox, Jenner's name would not be celebrated as it is today, and smallpox is far more contagious than diphtheria. On the whole, we are compelled to say that evidence of the value of prophylactic injections of the antitoxin is still wanting.

Is the antitoxin a specific against diphtheria in the sense advocated by Behring and Roux? By the question we mean, does the antitoxin neutralize the effects of the disease in the system and thereby insure recovery? In one thing all authors agree, *i.e.*, that the antitoxin does not kill the Loeffler bacillus or prevent its further development. In several of our hospital-cases the bacilli persisted in the throat for days and even weeks, notwithstanding the use of the antitoxin. Other observers have demonstrated that the bacilli not only persist in the throat but also retain their virulence for guinea-pigs.[7] Therefore the antitoxin cannot be called a specific for diphtheria in the sense that quinin is a specific for malaria. It certainly does not destroy the cause of the disease.

Mercury is called a specific for syphilis without

[7] Virulence for guinea-pigs should by no means be made the test for human beings, as it is in no sense conclusive. Each species of animal is a law only unto itself.

presumably destroying the cause of syphilis; in some way it neutralizes for the time being the syphilitic virus. It is difficult to say just to what extent this is true of the antitoxin of diphtheria. The children seem certainly to improve under its use, as every eye-witness can testify. And yet there is much evidence to show that the poison is not neutralized. Diphtheric nephritis and post-diphtheric paralysis are commonly assumed to be the result of the action of the diphtheric virus on the kidneys and nervous system respectively. Certainly the poison that leads to nephritis and paralysis is not neutralized by the antitoxin; so in the sense of mercury for syphilis, we can scarcely speak of the antitoxin as a specific for diphtheria. In a word, all our theorizing about the antitoxin is as yet without avail. The clinical fact is plain that a larger percentage of cases recover with it than ever did under any other form of treatment. This is the one practical fact, testified to almost universally, that makes the use of the antitoxin a matter of duty in cases of diphtheria in children.

And now a few words regarding the relations of the city to the question of the bacterial diagnosis of diphtheria. Modern custom has relegated to the city officials all over the world the task of dealing with the health-questions of the respective cities. The more advanced cities in Europe and America have already established disinfecting bureaux and stations for the destruction or disinfection of contagious material. Cincinnati has done little that is efficient in that regard. New York was the first city in the world to make adequate arrangements for the control of diphtheria and tuberculosis by means of bacteriologic examinations. The fact has been made perfectly plain that only by repeated bacterial examinations of the throat can we test whether a case of diphtheria has became free from infecting power or not. It is known that Loeffler bacilli remain in the throats of diphtheria-convalescents for many days and even weeks. One series of examinations at the City Hospital revealed the presence of the germ up to the fortieth day of convalescence; and repeatedly have we found the germ at the end of the third week. Nothing is more evident than that our present mode of placarding houses is not only unjust to the occupants, but also inadequate for public safety; many a family is seriously discommoded, its children kept from the schools—because the physician assumed a simple angina to be diphtheric. It has been my fortune more than once during the past five months to see cases which other physicians had called diphtheria, and which proved to be non-diphtheric. Patients have a right to demand bacteriologic examination before submitting to weeks of isolation, often with considerable detriment to business and always to convenience and comfort. The *ipse dixit* of the attending physician is by no means sufficient, be he who he may. On the other hand, placards are removed from houses four days after the physician signs a certificate that the patient is well, no matter whether the patient still be a source of public danger or not. The only possible control is the bacterial control—and it is now a matter of public necessity that every municipal health-department should be under the management of a professional and expert bacteriologist, with assistants and clerks who should devote all their time to the work in hand.

Cincinnati has recently applied salve to its own conscience by providing for the expenditure of $500 to pay for apparatus, office-work, and the salary of the city bacteriologist; while everyone knows that that sum is ridiculously inadequate to supply what is needed. Other cities have outstripped us. Brooklyn has adopted the same system as New York. In Boston the work has been done for the past seven months. In November and December of 1894 1002 cultures were examined by the city bacteriologist, who was relieved of all other work; in January, 1895, 842 cultures were examined. Boston has also provided for the manufacture of antitoxin, and has seven horses under treatment. The Philadelphia Board of Health has appropriated $15,000 to establish a bacteriologic bureau. In St. Louis the City Board of Health has for some months been examining for tubercle-bacilli and Loeffler bacilli, having established eighteen stations in the city for the receiving of specimens. New Orleans has for more than a year had a fully equipped and active bacteriologic bureau. Cleveland is supplied with antitoxin from the Western Reserve University. Buffalo has two professional bacteriologists who devote all their time to the work. Tubes for diphtheria-diagnosis are distributed to the thirteen police-stations of the city, and examinations are also made for tuberculosis. The tap-water and reservoir-water are examined daily; the mik and ice at proper intervals. Detroit has begun the work of bacterial diagnosis, and Indianapolis will fall into line this autumn.

COMMISSIONS TO PHYSICIANS UPON THE SALE OF ORTHOPEDIC APPARATUS, FROM THE MANUFACTURER'S STANDPOINT.

BY H. AUGUSTUS WILSON, A.M., M.D.,
CLINICAL PROFESSOR OF ORTHOPEDIC SURGERY, JEFFERSON MEDICAL COLLEGE; PROFESSOR OF GENERAL AND ORTHOPEDIC SURGERY, PHILADELPHIA POLYCLINIC.

IN the *Philadelphia Polyclinic* for September, 1894, I published a paper entitled "Can Physicians Honorably Accept Commissions from Orthopedic Instrument-makers?" in which I presented the subject from the standpoint of the physician. The position taken in that article is concisely stated in

the closing paragraph, in which I said: "If it is honest so to defraud the patients submitted confidingly to the care of the physician, it is just as right to ignore totally every point in the Code of Ethics that indicates to the contrary. If it is dishonest, and what physician can dispute it? are we not obliged, by the very words and spirit of the Code, so to proclaim it?"

A further consideration of the subject demonstrated that there is another standpoint from which the subject should be considered, namely, from that of the manufacturer or the business-man. I therefore sent a copy of my paper referred to, to a large number of manufacturers of orthopedic apparatus, artificial limbs, and trusses, with the request that they favor me with their views and opinions candidly expressed. The replies, from which extracts are used, form the basis of this article and are of great value in showing that too often physicians permit themselves to be classed, as Dr. Solomon Solis-Cohen has tersely denominated, "sales-agents."[1]

Illustrative of this I quote from the Winkley Artificial Limb Co.:

"We receive almost daily several letters from physicians, in apparently good standing, asking us how much commission we will pay them if they will send us a patient or an order for an artificial leg, and that they would like to have the limb, if purchased, either sent directly to them with one bill in full to show the patient, and one to them personally, less the commission; or that the limb be sent directly to the patient for the full amount and the commission sent to them. We recently received a letter from a surgeon having a large practice which read as follows: 'I now have five patients with amputated legs who are either ready or soon will be to wear artificial legs. I am going to have them place their orders with the firm that will pay me personally the largest commission. I do not care where they purchase their limbs so there is something in it for me. If you will pay me a larger commission than other firms, I will have them each and all place their orders with you.' We simply answered the latter by stating that we allowed no commission whatever, etc."

If this were a single instance, it would properly be considered as coming from some contemptible man besmirching the profession, the dignity of which it was his duty to uphold, and consequently beneath notice. In a number of replies from manufacturers, however, it is stated that they have had numerous requests from physicians for commissions; therefore the whole matter appears to come back to the starting-point, that in reality it is the physicians that make these commissions necessary. This view is substantiated by Sharp & Smith, who state:

"Would say if commissions are paid to them it is because it is agreeable to the physician who controls the order. We believe the whole matter rests with the physician."

George R. Fuller, of Rochester, New York, says:

"The custom amongst the profession of anticipating, accepting, and, I might say, exacting a commission on artificial limbs, trusses, etc., as a rightful legitimate fee, has become nearly universal, and I am glad to know that there is one of them who has the courage to brand the custom as a fraudulent one, an outrageous breach of the faith and confidence extended by the patient, and a violation of the Code."

The object of this paper is to reach those physicians who may not fully comprehend the importance of upholding the dignity of their profession, and who are acting as "sales-agents" in obtaining money under false pretence, and exposing the profession to just censure.

Mr. Frederick M. Bush says:

"I would divide physicians into three classes in the matter of orthopedics. First, those who know what they wish to do and how to do it, including the general mechanical design. Second, those who know what they want to do, but don't know how to do it, and leave the designing of the appliance to the instrument-maker. Third, those who don't know anything about it. For the first class, and the smallest, it is sufficient that the instrument-maker knows enough to follow the measurements and directions given, with perhaps an occasional suggestion from him on points strictly of mechanical detail. With such a physician it is ordinarily unnecessary for the instrument-maker to see the case; consequently all the business is transacted through the physician and the appliance is charged directly to him. Now his bills with his instrument-maker are probably settled monthly, and if his patients pay on the same terms, well and good. But suppose he is not always so fortunate, and some of his accounts run three, six, twelve months, and some he never gets. Physicians' bills are not always collected; where does he get the interest or make up the deficiency? Must he lose it out of his pocket because he has been unfortunate enough to have to advance cash? Is it not better and more equitable that he charge sufficiently more for such appliances to enable him to have a sort of sinking-fund from which he can reimburse himself for losses so caused? It seems so to me, and where is the need of secrecy? Business is business the world over, a church or a doctor's office, a theater or a dry-goods house should all be run on a business basis, and, though the superficial forms of advertising and dispensing commodities may differ, the same sound principles underlie success in any case.

"But does a solid conservative business concern take risks without hope of remuneration? Assuredly, no. *Somebody* has to pay; and the pay is proportional to the risk; and there is no thought of concealment.

"The second class of physicians should be governed by the rules which govern the first and third class. The more ability the physician requires of the instrument-maker and the less financial risk that is run, the less pay should the physician expect and the more should the instrument-maker get out of the work. The third class is not very hard to dispose of, because if they don't know anything, they can't do anything, and if they can't do anything they are not worth anything. Of course, a good many of the second class and all the third class had better not fool with orthopedics."

Of the duties of physicians to each other and the profession at large, Art. I ("Duties for the Support of Professional Character") of the Code of Medical Ethics says:

[1] "Shall Physicians Become Sales-agents for Patent Medicines?" by Solomon Solis-Cohen, M.D. Read before the Philadelphia County Medical Society, April 27, 1892.

"Every individual, on entering the profession, as he becomes thereby entitled to all its privileges and immunities, incurs an obligation to exert his best abilities to maintain its dignity and honor, to exalt its standing, and to extend the bounds of its usefulness."

Art. II.:

"There is no profession from the members of which greater purity of character and a higher standard of moral excellence are required than the medical; and to attain such eminence it is a duty every physician owes alike to his profession and to his patient. It is due to the latter, as without it he cannot command their respect and confidence; and to both, because no scientific attainments can compensate for the want of correct moral principles."

The following expressions of opinion condemning commissions are worthy of consideration:

"We would be glad to see all commissions abolished, as it opens the door to many methods which are rank injustice to patient, merchant, and doctor."—C. W. WHITE & CO.

"We have never under any circumstances allowed a commission on apparatus or appliances to anybody, in a business career of over fifty years, although we have had numerous requests to do so, and have likely lost a number of cases in consequence."—J. H. GEMRIG & SON.

"I wish to inform you that we are heartily in sympathy with the stand you have taken concerning this subject. We believe that the practice, prevalent as it is, of paying and receiving commissions, either from a business or professional standpoint, is radically wrong."—THE WINKLEY ARTIFICIAL LIMB CO.

"A physician has a right to be paid for his services, a lawyer his fee, a real-estate agent his percentage, a merchant for his ware. But when a physician is paid for his services and then demands a commission for sending his patient to an instrument-maker for an appliance, to such Dr. Solomon Solis-Cohen's term 'sales-agent' is properly applied. I have been struggling against it for years and probably lost the trade of numerous doctors on this account."—WILLIAM AUTENRIETH.

"We have read your pamphlet with interest and think the salient points well taken."—J. C. SCHNOTER & SON.

"It gives us great pleasure to indorse your views in regard to physicians taking commissions from instrument-makers. The correction of this abuse will enable all interested to retain their self-respect."—D. W. KOLBE & SON.

"I have never conducted my business on any percentage plan, and, unless I am requested by the physician, never pay him any. I have met with not a few who have asked for 'their' percentage, and have paid it rather than lose their influence."—A. GUSTAV GEFVERT.

"I enjoy the patronage of many a doctor who desires the welfare of his patient only, but also others who will not advise the use of my truss without expecting a commission. What will a man in my position do? Say no? I cannot well afford to give a commission, but losing the sale is out of the question on account of the influence felt afterward."—H. KLINGER.

"We do not offer commissions to physicians; however, when demanded, we are obliged to comply. When he orders an article and it is supplied by us as a piece of merchandise, it is sold as such; but when we must fit it, then in a business sense it is not mercantile to underhandedly offer or give a share of the profit."—ANONYMOUS.

"It seems to us that surgical instrument-makers are about the last ones whose opinions toward the rest of the world are of any account on this subject. No one believes more fully than we in the old saying, 'Let him who is guiltless throw the first stone.' Imperfection pervades mankind to such an extent that it is not reasonable to require absolute, simple purity in any one respect. Moreover, that which disposes of the whole subject, in our minds, is that the medical profession, as a whole, occupies in the social body a position so respected that it behooves itself only through its properly constituted bodies to lay down each and every feature of its Code of Ethics."—JOHN REYNDERS & CO.

"A few years ago I reduced the prices of artificial limbs about one-third and made an effort to keep the prices unvarying, without reduction or commission to anyone. I soon found that in order to get any business from the profession it would be necessary to allow a discount, and I have since made a practice of discounting 10 per cent. from the quoted prices on artificial legs. Taking a financial view of it, I am satisfied that it was a mistake to reduce the prices. I believe that I could more easily sell an artificial leg through the average practitioner at $100 with a 25 per cent. discount than I could by placing the advertised price at $60 or $70 with a 10 per cent. discount, with every assurance that the construction of the limbs would be the same.

"It is unquestionably true, however, that many physicians give the patients the benefit of the discount. Knowing that it is the rule for physicians to expect a commission or discount from the published prices of their products, it is perfectly natural that instrument-makers should make provision for it. These abuses are the result of the growing selfishness and corruption of the age, which, to a greater or lesser degree, enter into all classes and professions, and it will undoubtedly continue to increase so long as the possession of wealth is the chief ambition of mankind."—GEORGE R. FULLER.

"In some instances where physicians claimed that they had been allowed concessions of this nature by other instrument-manufacturers, I granted them. To such an alarming extent has the practice been carried that patrons have become aware of it (as they justly should) and have asked me to give them the benefit of the physician's commission. Requests of this nature, on many occasions, have put the physician, as well as myself, in a questionable position. Considered either from a professional or a commercial standpoint, the practice, I am convinced, is a most reprehensible one, and an immediate, earnest, honest effort should be made for its abolishment."—WILLIAM SNOWDEN.

Only three manufacturers have frankly and candidly written advocating the giving and receiving of commissions, and they do it by classing physicians, drug-houses, instrument-houses, and commission-houses as their profitable sales-agents.

"The legitimacy of authorizing drug-houses, instrument-houses, and commission-houses to obtain orders upon commissions has always been recognized and has never been placed within the pale of criticism. It has proved to be the most economical way by which articles of great benefit, service, and necessity can be made obtainable, with the least inconvenience to the parties needing them. Commissions are granted as compensation for time and labor expended in taking measurements, attending to the details of ordering goods, receiving them when finished, and properly delivering them to the parties for whom they are intended, and not as a bribe for favoritism, as I construe your paper to imply. I cannot see why physicians should not have the same privileges and obtain the same compensation if they perform the same services, especially as the commissions allowed do not affect the cost of purchase to the wearer. There is one strong argument in favor of granting com-

missions to physicians which should not be lost sight of, that is, that a very large proportion of physicians who receive commissions on orders for artificial limbs turn those commissions over to their patients, and thus place the cost of an artificial limb at a lower price than the patient would be able to buy if he bought directly from the manufacturer or if he passed the order through a commission-house, druggist, or shopkeeper."—A. A. MARKS.

"After duly considering the subject I will give you my candid opinion in the matter, 'Can Physicians Honorably Accept Commissions from the Manufacturers to Whom They Send Their Patients?' They can do so in many cases without the patients paying one cent more for the article than they would if they purchased it themselves. My opinion being based upon the following facts: The manufacturer produces an article which he finds he can produce at a certain price; to that he must add at least twenty-five per cent. so that he will have a profit, as it will cost him at least ten to fifteen per cent. to sell the article by agents, advertising, etc. Now we have the wholesale price. To give the retailer a profit there must be added another twenty-five per cent. on the wholesale price so that he can live. Now this twenty-five per cent. that is put on to protect the retailer is generally given in part, or the whole of it, to such people that can bring you trade, which people are generally considered by the manufacturer as his agents."—CHARLES A. BICKEL.

"Being a member of the noblest profession in the world, you are aware of the fact that, though physicians frequently go to considerable trouble in getting an apparatus made which will suit the case, they quite often receive but little if any remuneration for their services. This being the case, we believe that they are entitled to a commission, providing the patient or his relatives can afford to pay a good price for the apparatus. Should the patient and his relatives, however, belong to that class who are obliged to work hard for their daily bread, we believe that it is the duty of the attending physician to notify the manufacturer to that effect, renounce his commission, and leave the whole matter to the judgment of the manufacturer."—THE R. HYDE CO.

The relative position of physician and manufacturer is very difficult to define either from a professional or manufacturer's standpoint, for the reason that comparatively few physicians are sufficiently familiar with mechanics to order definitely an apparatus, or adjust it after it is made. Therefore the orthopedic-apparatus maker cannot be classed exactly like the apothecary or manufacturer of pharmaceutic preparations—nor can his services be entirely dispensed with by those physicians who even dispense their own prescriptions.

For instance, a physician having a patient requiring some form of apparatus, is very likely to send the patient to the manufacturer with a note saying, in effect: "I know my patient requires an apparatus of some kind, and I will ask you to apply what you think will accomplish the desired purpose." The physician's act in such a case would be to make the instrument-maker prescribe for the patient, *i.e.*, to practise medicine, but without a licence to do so. The instrument-maker, imbued with the idea that the physician does not wish to direct or prescribe mechanical appliances, is ready to assume full charge of the patients sent to him by a physician or coming to him through some other patient.

Many patients remain under the care of the instrument-maker for periods of months and years, never once having their physician see them to decide whether the mechanical requirements of the case are being properly fulfilled. Instrument-makers have told me that in cases, for instance, of rachitic bow-legs, when a correcting apparatus was applied and the patient sent back to the physician for approval, that he has told the patient to go to the instrument-maker if the apparatus got out of order. I have known cases of this kind to wear an apparatus for a year without any adjustment whatever, and yet is it not natural to suppose the growing child would change and improvement in the deformity would demand frequent adjustment which should be directed by the physician?

Many truss-makers tell me that they consider it impossible for physicians accurately to prescribe or adjust a truss because they do not carry a large stock from which to select. If this is true, it is difficult to understand how a physician can accurately adjust a splint for a fracture or a pessary for a deflected uterus. Again, there are instrument-makers who deprecate this assumption of authority. Mr. Frederick M. Bush, for instance, says:

"As to the instrument-maker turning doctor: He has no more right to do so than has the doctor to become instrument-maker. The functions of the two are totally different, and while the one may have ability of as high an order as the other, their educations so differ that they cannot become one and yet retain highest efficiency in either sphere. The physician should know the *mechanical theory* and the *therapeutic details*; the instrument-maker should know the *therapeutic theory* and the *mechanical details*. The physician takes the responsibility of prescribing the right thing; the mechanic takes the responsibility of correctly making the physician's prescription. A man brought in a steam whistle to have repaired and at the same time said he wanted me to make a brace for his child. He would not go to a physician, but wanted a brace after his own ideas plus what I might suggest. All right, said I, I am not repairing many whistles nowadays, but I will fix your whistle and make your brace, but when they are both done I don't care whether you put the whistle on the engine and the brace on the child, or whether you put the brace on the engine and the whistle on the child. I wash my hands of the whole matter. I don't want to play with things I don't understand, and it seems to me no one else should do so simply for the money there is in it. Outside of the honor and morality of the thing, it looks to me like very poor and shortsighted business, though I am well aware that the general public is fearfully gullible; however, 'you can fool some of the people all the time, and all the people some of the time, but you can't fool all the people all the time.' And when the instrument-makers try to do that, it results in their being found out by the intelligent public and winning the distrust and dislike of the decent physicians who would otherwise be their patrons."

The proper relationship of patient and physician is clearly defined in reference to all other therapeutic measures, and, by inference, also in reference

to mechanical appliances, both by the Code of Medical Ethics and by the medical laws of the various States. Sec. 15 of the medical laws of Pennsylvania states:

"Nothing in this act shall be construed to interfere with the manufacture of artificial eyes, limbs, or orthopedical instruments or trusses of any kind, or fitting such instruments on persons in need thereof."

The three conspicuous features of this clause are, first, that the medical laws of this State must not interfere with the manufacture of these instruments referred to. Second, there shall be no interference with the fitting of these appliances, presumably by the maker or seller. The third feature describes the class of people for whom the appliances are made and upon whom they are to be fitted without interference "on persons in need thereof.

The question as to who is to decide what persons are in need of appliances is necessarily not discussed, for the clause referred to is part of an act, a part of the title of which says "to provide for the examination and licensing of practitioners of medicine and surgery, to further regulate the practice of medicine and surgery."

For example, Sec. 9 of the laws of Arkansas says:

"That any persons who shall prescribe or administer medicine for or shall in any way treat diseases or wounds for pay shall be deemed physicians and surgeons under this act, and therefore entitled to all the privileges and penalties which are defined by the law."

With different wording, but the same idea, the same condition exists in Arizona, California, Colorado, Delaware, District of Columbia, Illinois, Iowa, Minnesota, Missouri, Montana, Nebraska, New Jersey, New Mexico, New York, North Dakota, Oklahoma, Oregon, Pennsylvania, South Dakota, Utah, Vermont, Washington, West Virginia.

Georgia is especially explicit in Sec. 2 of its medical laws:

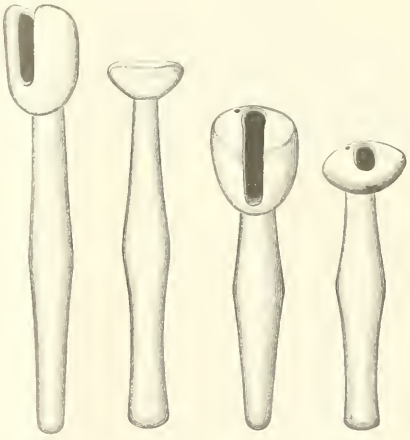
"Be it further enacted, that for the purpose of this act the words 'practise medicine' shall mean to suggest, recommend, prescribe, or direct for the use of any person any drug, medicine, appliance, apparatus, or other agency, whether material or not material for the cure, relief, or palliation of any ailment or disease of the mind or body, or for the cure or relief of any wound, fracture, bodily injury, or other deformity, after having received or with the intent of receiving therefor, either directly or indirectly, any bonus, gift, or compensation."

If these extracts from the medical laws of twenty-five States mean anything, they mean that when a patient goes confidingly to a physician it is for the reason that the patient believes his physician to be of that high order that everyone esteems and honors. He naturally believes that in the event of his physician not feeling sufficient confidence in his own knowledge, experience, or ability, he will consult with some other physician, and that he will then direct, prescribe, or order such form of remedial measures as will be of benefit in the patient's case. He should not believe, nor should he have cause to believe, that his physician will order for his patient mechanical appliances from that manufacturer who will secretly pay him the largest commission. Equally reprehensible is it to permit a mechanician to endanger the life and health of any patient by prescribing apparatus, the requirements for which can only be disinterestedly comprehended by one learned in the laws of disease.

A SUGGESTION BEARING UPON THE TREATMENT BY A NEW METHOD OF PERSISTENT VOMITING.

BY CHARLES L. GREENE, M.D.,
OF ST. PAUL, MINN.,
INSTRUCTOR IN CLINICAL MEDICINE IN THE UNIVERSITY OF MINNESOTA, VISITING PHYSICIAN TO CITY AND COUNTY HOSPITAL AND UNIVERSITY FREE DISPENSARY.

IT is with considerable diffidence that I propose a method of treating a condition that has ever been a reproach to the medical profession. Each year sees patient after patient die from the effects of uncontrollable vomiting, and no means at present within our reach meets our need in the really severe and dangerous cases. The following plan of treatment is crude and undeveloped, and the plan is suggested because I have been vainly awaiting for the past year an opportunity to test its real value, and because, should it prove useful, further delay would be inexcusable. Cases of this kind are uncommon, and my practice is along lines which make them of even greater rarity to me than would be the case if I were in general practice.



Showing special tube and ordinary tube. Full size.

It is evident that in casting about for a way to

overcome this formidable disease or symptom we must first consider the means through which it proves fatal. These are chiefly two:

(a) Actual exhaustion from the violent and persistent retching.

(b) Starvation from the lack of power to secure and retain a proper amount of nourishment.

Rectal feeding may partially overcome the latter, but is unsatisfactory and inefficient, while in many cases no known measure will overcome the former. The treatment, to be efficacious, must, therefore, prevent the act itself, and thereby insure the reception and retention of food.

In considering the anatomy and physiology of vomiting we find a suggestion that when followed out may furnish us with a practical means of satisfying our needs in this direction, for whatever may be the cause of the act, whether local or reflex influences excite it, the actual process remains the same, and consists simply (a) in a slight contraction of the muscular fibers of the stomach itself, bringing about closure of the pylorus and opening of the cardiac orifice; (b) a coincident and vigorous contraction of the muscles of the belly-wall; and (c) a rapid and forcible inspiration, with closure of the glottis, which fixes the diaphragm and furnishes a rigid surface, against which the stomach is vigorously compressed and thus relieved of its contents. Now, it appears to be admitted by modern physiologists that unless a stomach be overfull, overflowing in fact, vomiting cannot be brought about in adults without fixation of the diaphragm, and this fixation we find to be dependent upon the rigid ribs and pressure excited by the deep inspiration, and the column of air retained by the closed glottis. If, then, this be correct, and we open the trachea, our patient certainly cannot vomit, and if we could secure the patency of the trachea by intubation we would soon have a means of partial or complete control.

Acting upon this theory the modified tube, herewith represented, has been constructed by Tiemann after the plan submitted by me, and would seem to meet the indications in so far as preventing glottic closure is concerned, and it is also intended to prevent complete descent of the epiglottis, which in the ordinary O'Dwyer tube would close the upper opening and thus defeat its purpose.

It will be noticed that the tube is like that of O'Dwyer's in its general outline, but the head is very much greater in height and there is an opening upon its anterior face, or rather its posterior aspect, as viewed *in situ*. This opening is intended to allow free egress and ingress of air whatever the position of the epiglottis. Applied to the cadaver this tube fully meets the indications, and should be borne, one would suppose, with little more discomfort than would be caused by a tube of the ordinary pattern. O'Dwyer's articles have amply demonstrated the remarkable tolerance of the laryngeal structures, and many instances are cited by him in which tubes of large caliber were borne with little discomfort for a long period. The tube figured is probably too long in the shank and too heavy, and, as suggested by Tiemann, should properly be made of vulcanite rather than of metal.

The association between the center for glottis-closure and that of vomiting is so intimate as to suggest the possibility that mere prevention of approximation of the bands would prevent the proper carrying out of the remainder of the act, and if this were the case the ordinary tube would be the proper one to use. It would seem probable, however, that any closure of the air-passage through whatever means brought about would admit of the completion of the act, and that it were absolutely necessary to secure a clear passage for the air and thus rob the diaphragm of its rigid base of support.

The applicability of this method of intubation to severe cases of hiccough or pertussis would also suggest itself.

The process of intubation is so simple and well understood at the present time as to offer no difficulties to most of us, and but little hardship would be inflicted upon a patient by this procedure.

I have experienced much difficulty in securing a substantial basis for the theory advanced, and confess myself doubtful upon several important points. The observations of surgeons upon the occurrence of vomiting after tracheotomy would be of especial value here, and will, it is hoped, be forthcoming, for should the tube fail through improper construction, or for other reasons, I believe that tracheotomy would certainly be a justifiable procedure in the terrible disease or symptom under discussion.

There are many factors that will prevent any very positive statements for or against the proposed treatment until the test of actual experience has been instituted. Dr. Henry Sewell, of Denver, whose work in physiology is widely known, has cautioned me against a too ready acceptance of expressed views of authorities, and calls particular attention to the separate existence of the center of glottic closure and that of the act of vomiting itself, indicating the possibility of independent action, though so far as one can ascertain they are supposed to be invariably in harmony. The want of definite pathologic knowledge, the possibility of overaction of the pharyngeal constrictors, and many other things may be thought of as possible disturbing factors, yet, nevertheless, it will be seen that there are *possibilities* in the line of treatment submitted, and the opportunity to test it will not be lacking to some of us in the near future. The tubes may be obtained from Tiemann, and the introducer is that ordinarily used.

I conclude with an apology for this necessarily indefinite and incomplete report, and the hope that we shall find something of real utility in the application of intubation or tracheotomy to cases of severe and intractable vomiting.

CLINICAL MEMORANDUM.

A CASE OF LUPUS VULGARIS.[1]

BY LOUIS MACKALL, JR., M.D.,
OF WASHINGTON, D. C.

WHEN I first saw this patient I thought that her case would be an interesting one, and I had a photograph taken to show her condition at that time. The following is the history:

Ida E., aged eighteen years, resides in a canal-boat at the Maryland Dock. About six years ago she was treated at the Emergency Hospital for nasal catarrh. She described her nose as then being slightly swollen, and very much stopped up with crusts. The physicians there gave her various snuffs to use. She then went to Hancock, Md., to live. While there, about five years ago, she says the present condition began on the left ala of her nose as a pimple that rapidly formed into a crust. The doctor that treated her there told her that she had a "cancer," but made no effort to remove it. It is my opinion, though I have no absolute proof of it, that this is one of those interesting cases in which the disease commenced on the mucous membrane of the nose, and that the catarrh for which she was treated at the Emergency Hospital was the result of the lupous condition already existing. The entire nose disappeared in about three months, the left side being eaten away first, then the right; then the disease attacked the rest of the face, and continued to spread up to the time she came under my care, when the face was one immense scar covered with crusts and nodules. The entire nasal cavity was filled with crusts and tuberculous ulcerations. There was a cleft in the horizontal portion of the palatal bone and in the palatal process of the superior maxilla. She says that she did not have this cleft when she was a child. We are informed by all authorities that lupus does not attack the bones. I suppose that they would account for the cleft in this case by saying that the soft parts ulcerated and left the bones exposed, and that these necrosed as a result. When I first saw her there were some periosteal nodes on the right ulnar and left tibial bones. These disappeared for a time; but those on her leg returned, and again disappeared under treatment. During the period of her illness she has been confined to bed only three days. I mention the fact to illustrate how much these patients can endure and yet go about. She menstruated for the first time last month. The family history does not furnish any information. The girl says that her mother died of dropsy at the age of forty-nine years, and that she had a cough when she died. Her only sister is living and presents a very healthy appearance. She has no signs of pulmonary or of laryngeal trouble. She has been under my treatment for several months past, and though she comes to my office very irregularly she has continued to improve very rapidly.

I shall not weary you with a detailed statement of my treatment, which has nothing unusual in it; but I will only give a brief synopsis of the method adopted. I have been giving her tonics of various kinds, alteratives, and as nutritious a diet as possible in her station. I removed all crusts, and then applied Unna's plaster to her face, and a solution of salicylic and carbolic acids of the same strength to her nasal cavity until the tubercles were completely broken down; I then dressed the raw surfaces with a solution of hydrogen dioxid.

There have been several classifications ot lupus; but the one generally accepted divides it into two broad classes, lupus vulgaris and lupus erythematosus. It is not always so easy to decide to which of these two simple classes some examples belong. I have seen patients in the clinics of Sir Jonathan Hutchinson which even he was not able to classify. I consider the most simple classification of a disease always the best. Lupus is one of the few true tuberculous ulcerations of the skin. It is an infectious disease caused by a specific micro-organism, the bacillus tuberculosis. Koch has proved this fact by finding the bacilli in small number in the nodules characteristic of the disease. The bacilli, according to Moullin, occur in the shape of very thin non-motile rods from two to eight micromillimeters in length, and are found in the interior of the giant-cells and epithelial cells, but they are so few that many distinguished authorities deny that they can be the cause of such a destructive ulceration. Both forms are very chronic.

[1] Read before the Clinico-Pathological Society of Washington, D. C.

Lupus vulgaris is very common in England. It is even estimated to form about 2 per cent. of all cases. But I think that statistics on that point are not reliable. Both forms of the disease are rare in this country. Lupus vulgaris is much more common than lupus erythematosus, and, as my case belongs to the former class, I shall confine myself to the description of that variety.

Lupus vulgaris, as a rule, begins in childhood, very rarely commencing after the fourteenth year, although there are some few cases on record beginning as late as the thirtieth year of life.

The disease generally begins on the face, attacking first the cheek or nose. It is usually unilateral, although sometimes it presents as symmetrical an appearance as lupus erythematosus. It sometimes attacks the limbs, buttocks, and mucous membranes. There is a case reported by Mathews Duncan in which it attacked the vulva, but authorities generally believe this to have been a case of syphilis. The face is the favorite locality for all forms of lupus, and it generally takes for its victim one who has a fair complexion. It is more common among females than among males. Crocker describes a typical case as commencing with a few scattered or grouped spots about the size of a pin-head, of a dull-red color, on the level, depressed, or raised, above the normal skin. They do not disappear on pressure. These spots are gradually developed into small tubercles which have a semi-translucent aspect and are of a brownish color and present the appearance of apple-jelly.

These tubercles, sometimes rapidly, sometimes slowly, are developed into a red patch or patches raised distinctly above the skin, and having a firm edge. At this period there is generally a scaliness present. The growth of the disease varies considerably. It has variable periods of improvement; the older one gets, the more frequent is there a tendency to quiescent periods. I think that this is so because the patients learn to take better care of their general health, and learn by bitter experience to avoid exposure of all kinds. Associated with the lesions on the face at a later period of the disease they often present on the limbs subcutaneous nodules that finally become adherent to the skin itself. In those who have a strumous diathesis they often present abscesses, periostitis, caries, etc. Joints sometimes become crippled from the contraction of tendons in the cicatrices.

The age of the patient, the scarring, the apple-jelly nodules, and the persisting spreading render the diagnosis easy.

It is very seldom that there is a complete cure after the places are apparently healed up. If the patient becomes a little run down in health the disease recurs each time, destroying more tissue until the face becomes one complete scar.

Early diagnosis is of extreme importance, for it is only in those cases in which it is made that we may hope to cure the disease by prompt eradication.

The treatment is divided into constitutional and local. The latter is, by far, the more important; but the constitutional should not be neglected, and everything possible to improve the general health should be done. Improvement in assimilation is the great aim. As nutritious a diet as is permissible with perfect assimilation should be allowed. The patient should be surrounded by good hygienic conditions, and he should avoid exposure to the weather, as cold is considered one of the predisposing causes. Cod-liver oil, iron, hyphophosphites, and other tonics (when they agree with the alimentary system) are often beneficial, because the disease is so often associated with the strumous diathesis. For a long time past all attention has been given to local treatment.

Koch's lymph has revived great interest in the general treatment. The great object aimed at is complete removal of the tuberculous tissue. We endeavor to do this by many different methods; but the principle of them all is the same. Some surgeons use the Volkman spoon. Perhaps this is the most popular method. When the spoon is used great care should be taken to use it thoroughly at the margins of the sore. The actual cautery is applied by some after using the spoon, and by others it is applied without the previous use of the spoon. Afterward the sore should be dressed with one of the various antiseptics. Various chemicals have been employed by different surgeons. Among those which are most deserving of mention is Unna's plaster, which consists of salicylic acid and phenol as its principal ingredients. The phenol is used because of its anesthetic power. This plaster is called after the celebrated Unna (of Hamburg), who used it a good deal. The application should be renewed frequently until the nodules break down and free suppuration sets in. Some antiseptic ointment should then be applied to the sore. Some surgeons use chromic acid and others caustics. The result does not so much depend upon the caustic selected as upon the care taken by the physician. Recently some experimenters have endeavored to produce erysipelas in the sore, and they claim that the experiments have produced some good results; but I have had no experience with this method. There can be no doubt that Koch's lymph has proved beneficial in some cases. It has rarely failed to produce either a general or local reaction, and generally both. Some of the London surgeons have combined the surgical method and Koch's treatment with very good results.

NEW DEVICE.

A NEW EXTRACTOR FOR THE REMOVAL OF INTUBATION-TUBES FROM THE LARYNX.[1]

BY DILLON BROWN, M.D.,
OF NEW YORK.

THE greatest difficulty in the technique of intubation is the removal of the tube, and it is almost always during efforts at extraction that the larynx or neighboring soft parts are injured. Either the sharp point of the extractor is forced into the soft tissues and a false passage is made or the tip fails to enter the tube and passes along the outside of it, within the larynx, so that when the blades of the extractor are widely opened and withdrawn they divulse the larynx, and the tube sinks out of reach.

On account of these objections many have entirely abandoned the operation; others remove the tube by position and by pressure over the trachea; and others

[1] This device was exhibited to the American Pediatric Society, May 27, 1895.

remove it by the string, one end of which is attached to the tube and the other fastened to a tooth or brought out through the nose. The dangers and disadvantages of such methods are obvious.

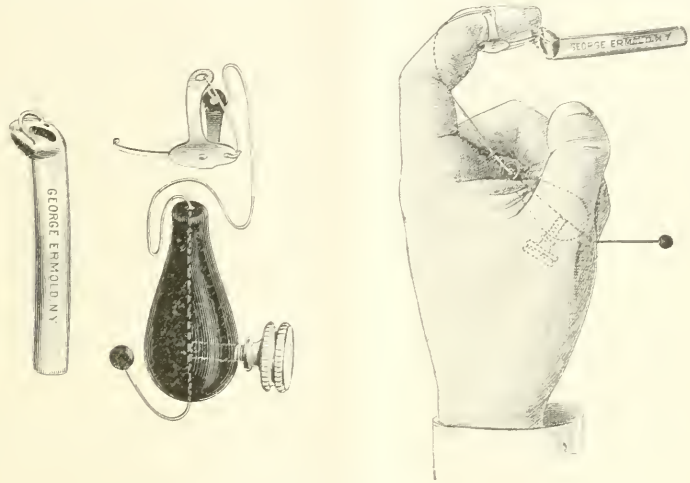
These serious drawbacks to this most brilliant operation have led me to modify the tubes and to devise the extractor which is described and illustrated in this paper. A wide experience in teaching men who are unfamiliar with the operation has demonstrated to me that a large proportion of them find much difficulty in removing the tube with the old extractor, and many of them never succeed in doing it quickly and skilfully. With the new instruments rarely does a man have any trouble in quickly extracting the tube—even in the beginning, and without practice. And it seems to me that a nurse could be easily taught to take out the tube after a few minutes' instruction on the cadaver.

The new tube is as efficient as the old one; it does not increase the difficulties of deglutition—rather the reverse—and it does not interfere with the older methods of extraction. It has a stiff wire loop attached to its head (see illustration), which is firmly fastened to one side, rises about one-eighth of an inch, closely follows the posterior edge of the head of the tube, and is finally fastened to the corresponding point on the opposite side. This makes an *eye*, bent posteriorly, which is easily and almost unavoidably caught, and which does not interfere with the opening in the tube or with the epiglottis. The posterior part of the head of the tube is scooped out, making an antero-posterior groove, which still further facilitates the catching of this eye.

The extractor is a simple *hook* fastened to the finger (see illustration), so that the tip is held moderately firmly against its palmar surface, and far enough away from the ball to prevent its interfering with the sense of touch. The hook is fastened to the finger by the flexible metal ring, and is removed by the string after it has caught the tube. Pulling on this string brings the ends of the metal ring together and holds it firmly on the finger, and it is kept steady by wrapping the string once around the index finger and grasping the wooden handle in the palm of the hand. The string can be sufficiently shortened by means of the screw to enable one to do this with ease.

On feeling the tube, and pressing firmly down and back, it is almost impossible for the *eye* to avoid slipping between the finger and the *hook*, and the shape of the latter prevents it from escaping. On withdrawing the finger the tube must come with it. It is evident that this extractor not only greatly simplifies the removal of the tube, but makes it impossible to do any damage to the larynx during this procedure.

These tubes and extractors are made by Mr. George Ermold, 312 East Twenty-second Street, New York, and my thanks are here extended to him for the skilful manner in which he has carried out my suggestions.



The Dillon Brown Extractor.

MEDICAL PROGRESS.

The Cerebral Fissures of Two Philosophers.—In a paper read by title before the American Neurological Association, Dr. Burt G. Wilder stated some results of a study of the brains of two philosophers, Chauncey Wright and James Edward Oliver. These men were recognized as superior in character and mental power. They were mathematicians, and thought deeply upon the broadest questions. Wright was more a writer and general critic; Oliver was more a teacher of advanced mathematics. The latter was slight in frame and alert in action, the former was large in person and slow of speech and movement. Wright's brain weighed 1516 grams (53.50 ounces), Oliver's 1416 (49.94 ounces). Although above the average of male brains (about 1400 = 49.4 ounces), greater weights are not uncommon even among less intellectual persons. In both, the frontal region is unusually high and wide; the unprecedented squareness of Wright's

suggests some post-mortem pressure, of which, however, there is no record. In both, the supertemporal fissure is longer than common. Oliver's fissures present several individual variations from the common type, but none comparable with the two rare conditions in Wright's, already noted by Dwight (*Amer. Acad. Arts and Sciences, Proceedings*, xiii, 210–215, 1877), and by Wilder (*Journ. Nerv. and Mental Disease*, xvii, 753–4; *Amer. Neurol. Trans.*, 1890; *Ref. Handbook Med. Sciences*, viii, 158–159, ix, 108). The complete interruption of the central fissure has been observed in a dozen cases or more. The simplicity of the fissures and the width and flatness of the gyres are paralleled in the Cornell collection only in the much smaller brain of an unknown mulatto (No. 322, *Ref. Handbook*, viii, Fig. 4767). Some approach to this condition occurs in Ruloff, a murderer (No. 965), and perhaps in a German shown by Wagner ("Vorstudien" Taf. vi, Fig. 2) after Huschke ("Schädel, Hirn und Seele," Taf. v, Fig 2). If fissural simplicity and gyral width and flatness are family characteristics, or correlated with Wright's mental and physical deliberateness, then light may be thrown upon the problem by the conditions to be observed in his blood-relations or in others similarly "slow but sure" in thought, speech, and act. As a close mate for the brain of Chauncey Wright has not been found in that of James Edward Oliver, the contemplated full account of it need not longer await the death of other moral and intellectual compeers. Such exceptional cases will always command attention. But all estimates of the extent and significance of their peculiarities will be only provisional until the careful comparison of *many average* brains supplies one or more types or standards. This necessity should be kept in the public mind.

Fatal Hematemesis from Ulceration of a Gall-stone into the Duodenum.— DUFFETT (*British Medical Journal*, No. 1794, p. 1090) has reported the case of a man, fifty-two years old, who had suffered from biliary colic for nine years. On several occasions, after the attacks had subsided, gall-stones were found in the stools. The last attack had occurred nine months before coming under observation, and had been exceptionally severe. An operation had been advised, but had been declined. The patient came under observation for an attack of hematemesis, in which more than a pint of dark, clotted blood was ejected. The skin and conjunctivæ were jaundiced, and there was intense irritation of the skin. The abdomen was flaccid and easily palpable, but no enlargement of the liver or gall-bladder could be made out. The bowels were constipated, the stools clay-colored, and the urine contained bile pigment. Shortly afterward, after overexercise, the man vomited up a pint-and-a-half of semifluid, dark blood, and two hours later an additional half-pint; besides, the bowels moved unconsciously and the stools contained partially decomposed blood. On the following day the patient complained of faintness and dimness of sight, and soon afterward vomited three pints of clotted blood, one clot representing a distinct cast of the pyloric end of the stomach and the upper part of the duodenum. A further hemorrhage was followed by death. Upon partial post-mortem examination the liver was found hard and slightly contracted. The stomach contained a quantity of blood, its mucous membrane was thick, and there was no trace of ulceration. The pylorus was normal. The gall-bladder was small and contracted and empty, and its walls thickened. A finger introduced into the gall-bladder passed easily into the duodenum. Lying loose in the duodenum was an unfacetted gall-stone with a quantity of blood. The edges of the opening were soft and probably of recent date. The gall-stone measured three-quarters by one-half inch, and weighed when dry forty grains.

Endogenous Formation of the Malarial Parasite.—LEONARD (*International Medical Magazine*, vol. iv, No. 4, p. 265) has been able to study the endogenous formation of the malarial parasite by means of photomicrographs prepared from fresh malarial blood, kept at the temperature of the body with the aid of a warm stage, and magnified two-thousand diameters. The free, non-pigmented, hyaline ameboid form is a minute globular hyaline mass, of a slightly different density from the surrounding medium, varying in size, but seldom exceeding one-fifth the diameter of a red corpuscle. It is found attached to a red corpuscle, and may be seen in active ameboid motion within the red corpuscle. It represents the first stage of the life-cycle of the malarial hematozoon. The intra-corpuscular pigmented form is developed from the non-pigmented ameboid form after it has entered the red corpuscle, and contains a pigment—melanin, which is a derivative of the hemoglobin of its host collected in a granular form. It varies in size, sometimes gradually increasing until it occupies the entire corpuscle. The extra-corpuscular pigmented form is the intra-corpuscular pigmented body which has come out of the red corpuscle, either by the extrusion of the individual or by the formation of a number of these bodies within a corpuscle and its subsequent rupture. The crescentic body or malarial crescent is probably a resting or spore-form, and is found generally in cases of malarial cachexia.

A Pregnancy of Ten Months.—At a recent meeting of the Chicago Gynecological Society DR. F. A. STAHL reported the case of a German-Bohemian woman in which the fifth pregnancy terminated 302 days after the last menstruation. Twenty days before there had occurred pains similar to those of labor, but they gradually ceased. The sacral promontory was exaggerated, and the antero-posterior pelvic diameter of the inlet in consequence diminished. The fetus was large and occupied the first position. Version was with difficulty effected, and the passage of the after-coming head through the superior strait required expression and traction, during which the child died. The mother suffered a deep laceration of the perineum, involving an inch of the wall of the rectum.

Recovery from Hyperpyrexia Accompanying Pleurisy and Pneumonia.—STANLEY (*British Medical Journal*, No. 1794, p. 1144) has reported the case of a woman, thirty years old, in which in an attack of pleurisy and pneumonia the temperature rose on two occasions to 114°. At these times the patient complained of complete loss of sensation in the hands and feet, and requested to have have them rubbed. Absence of delirium was noted.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

SATURDAY, JULY 6, 1895.

THE PERFECTION AND THE RESOURCES OF THE HUMAN MACHINE.

It is so easy to notice defects, either in others or in ourselves. In others they seem to stand out in bold and cheerful relief, while in ourselves they thrust themselves upon our notice in the most annoying manner. When we agree with the Psalmist that "we are fearfully and wonderfully made," it is our fearful liability to break down or get out of order that we are chiefly thinking of. Perhaps this is but natural, for it is always the evil in things that most sharply impresess us. Comfort is a passive, hazy sort of sensation compared with the clear-cut acuteness of pain. Besides which there's no need to pay any attention to the good qualities of things. They'll never bother you. "Well enough" can be safely "let alone." Ill, however, demands our instant attention and action.

Health will take care of itself, disease must be cured at once if possible. A healthy man doesn't know that he has such a thing as a stomach; a dyspeptic doesn't know that he has anything else. Hence pain is the great educator, the chief spur to investigation. If there were no suffering there'd be no medicine, no anatomy even; pathology is the starting-point of physiology. So long as all goes well and smoothly we care nothing about our interior make-up, but let "dys-" anything develop, and the digging and probing begin at once.

Does not this state of affairs have a strong, though unconscious, influence upon our mental attitude as a profession toward the human machine? We are kept so continually engaged in patching and tinkering at it that we are in danger of coming to look upon it as a bundle of defects. The laryngologist declares that a healthy (or artistically symmetrical) nose or throat is rare; the gynecologist deplores the faulty plan of construction of the uterus and vagina; the oculist announces that a "normal eye" is to be found only in the text-books; and the bacteriologist regards the young human body merely as a congenial culture-medium for the Klebs-Loeffler and the adult one for the Eberth bacillus. We are prone to rate our patients much as Falstaff did his recruits, "Tush, tush; mortal men, food for powder, food for powder!" only the grains of our "powder" are alive and wiggle, and assume a variety of comma-shapes. Even as sanitarians we seem to delight in populating the heavens above, the waters, the earth beneath, the dust of our streets, the food upon our tables, with hosts and swarms of tiny savages to whom the human body is a helpless prey whenever pounced upon. Existence would be impossible but for germicides, say we. It is positively dangerous to be alive! In short, we often forget that the human body is not a pulpy victim of circumstances, but the toughest, most resisting, most marvellously adaptable, and most ferocious organism that the sun shines upon. It can flourish where nothing else can, and fatten on a diet of any other organism that can be mentioned, not excepting the pathogenic bacilli.

In the first place, the lesson that the schoolma'am is so fond of impressing upon the infant mind, "Man is physically the feeblest of all animals, but by his superior brain he masters all," is utterly untrue. Man is physically the finest, most dangerous animal in the world. Not a bird or beast or even fish that he can't beat at its own game, if he sets himself about it. The Blackfoot Indian will run down a deer, knife in hand; even the "tireless wolf" can be overtaken and killed if you can only keep on his trail. The negroes of Mozambique spring right into the water and attack sharks, armed only with a short knife. The Sikh will face a tiger with his short, heavy scimeter, and a thous-

and tests abundantly demonstrate that civilized man is as much superior to the savage as the latter is to the animals. Club or sword in hand, man is a match for the most ferocious beast of prey in a fair, stand-up fight, and the club or its descendant is as much a part of us as our bones or skin; but for it we should never have allowed our teeth and claws to degenerate into such feeble objects. Its use has made us right-handed; right-handedness has specialized the cortex to such a degree that speech was possible, and speech makes thought possible. So that our mental superiority is purely an outgrowth and a part of our muscular superiority. In the language of Tommy Atkins in Kipling's ballad, *homo sapiens* is "a pore benighted heathen, but a fust-class fitin'-man," and two-thirds of his virtues, moral, physical, and mental, are the fruits thereof. And yet we talk of him professionally as if he were a clam without a shell.

In the second place, there is no known organism that can defy the elements as he can. Any zoologist will tell us that no other mammal and no bird has one-half the geographic range that the human species has. His faithful friend, the dog, will accompany him almost everywhere, but only by having his food, shelter, and even clothing provided for him by the superior species. We speak of being "as rugged as a bear," but it takes three distinct species of *Ursus* to keep pace with man from the tropics to the pole. A dozen or more species of deer are required for the same match. Even the domestic animals when carefully housed and fed by him are far inferior in toughness, and one of the greatest obstacles to his progress in many regions is the impossibility of finding any beast of burden or milk-giver that will live in the climate with him. The only species that can even enter the lists with him is the blue-winged teal, and he is disqualified at once by the fact that he is the "very moral" of a fashionable valetudinarian, spending his summers in Labrador and his winters in Florida.

Much of this faculty is, of course, due to man's power of constructing shelter and clothing for himself, but still more to his worldwide range of food-materials. Look at him in the tropics, subsisting on rice and fruits, only sawdust and shavings under his boiler, so to speak; in the Arctic regions, gorging upon seal-meat and whale-blubber, firing his engine up to the explosion-point. His instinct meets the situation. A Hindoo would look with loathing on the eighteen-or-twenty-pound meal of seal-blubber of the Eskimo, and we carnivora of the temperate zone would hesitate about attacking it. Yet a professional friend of ours has assured us that on a mid-winter trip with dog-sledges near the Alaskan shores of the Arctic Ocean he positively lost all appetite for bread, lean meat, fruit, sugar, etc., and cared for nothing but the unsalted dried salmon and rancid seal-oil which formed the food of both his Eskimo guides and their dogs. A pint of the latter beverage carried in the uncured skins of the animal, he declared, was as refreshing and appetizing after a long day's run as hot coffee with cream. When we remember that the whole party was sleeping out on the ice every night, in a temperature of from 30° to 60° below zero, with no shelter save their reindeer-skin, night-bags, and their sleds piled up on the windward side of them, we begin to see the reason for this almost pure hydro-carbon diet. There was not room in the human stomach for enough of any other material to furnish heat to keep up the bodily temperature against such fearful odds. But think of the splendid adaptability of the creature! Our respect for the human machine becomes immeasurable. At the other extreme, look at Stanley and his Somalis, laboring forward day after day in heat and fever-fog through the jungles of the Congo, everything carried on the heads of the men (no horses, oxen, or even asses could stand the work and the climate), all on a diet of roasted bananas, sugar-cane, and green corn.

The same toughness and faculty of adjustment manifest themselves even more strongly when we come to consider the unfavorable environment in which man places himself in the various occupations of civilized life and the strain of city surroundings. Scarcely a trade or occupation can be mentioned in which most of those engaged in it are not vigorous, healthy, and long-lived. We speak of "occupation-diseases;" it is true there are such, but none of them ever affects more than a small percentage of those engaged. Even when they occur they are symptoms of lowered vitality, either local or general, on the part of the sufferer in most cases. Many of them can be avoided entirely by cleanliness and observance of the ordinary laws of health. "Painters' colic," for instance, is caused entirely by eating the mid-day lunch with unwashed hands or upon spattered boards or tables, and can be completely escaped by always thoroughly cleaning the hands before eating. "Phosphorus-necrosis" never at-

tacks a healthy mouth or jaw, and can be prevented by the prompt filling or removal of decaying teeth. "Chimney-sweeps' cancer" finds a perfect prophylactic in the daily use of soap and water. It was long supposed that in "miners' consumption" and "printers' phthisis" and "knife-grinders' asthma" we had a group of diseases, practically necessary risks of the three occupations, but the first is completely out of the list now, first, because the death-rate from tuberculosis is no higher among miners than in the rest of the community, and, second, because a similar carbonized condition of the lungs is being found to exist in a considerable proportion of dwellers in manufacturing towns and smoky cities without any corresponding increase in the prevalence of pulmonary tuberculosis. It is also more than suspected that the irregular hours and worse habits of the "typo" have much more to do with his "consumptive" tendency than the dust of dried printers' ink in which he works.

Of all occupations probably none has had a blacker reputation for unhealthfulness, both popularly and professionally, than that of the coal-miner. Working as he does hundreds of feet under ground, in wretched little burrow-like passages, in an atmosphere foul with coal-dust, fire-damp (CH_4), "choke-damp" (CO_2), and powder-smoke, exposed to the most frightful accidents by explosion, by water, by falling rock, surely no mortal organism can long resist the pressure. When we further remember that in the English mines the galleries in which he works scarcely average *four feet* in height, and that in coal-getting ("holing under" the seam) he often works for yards at a stretch in a space *two feet or less* in height, so that he has to lie flat on his side to swing his pick; that the mine is usually both warm and damp, so that he emerges dripping wet at the pit-mouth into an atmosphere from 30° to 60° lower; that his dwelling is a mere barrack, usually badly built, badly drained, and overcrowded; that his wages are so irregular that life with him is generally "either a feast or a famine," we marvel that the breed doesn't become extinct. No wonder it was for long years rated as an extremely unhealthy occupation. The question has been carefully investigated within the last ten years, however, with the astounding result that "the comparative mortality-figure of these laborers is considerably below that of all males, and, if we exclude accidents, only slightly exceeds that of the most healthy class, the agriculturalists." (Dr. Ogle, Census Statistics of 1881.) The same authority also reports that "his mortality from phthisis is remarkably low." The Labor Commission sums up its findings in the sentence: "The weight of evidence seems to be against the idea that coal-mining is an unhealthy occupation." That veteran gladiator, the human body, has risen to the emergency again and conquered just as it used to do in the ages when it lived on bear-meat and ground-nuts by choice, mussels and sea-weed by necessity, and sucked its paws when it could get neither.

The soap-renderer, the hide-scraper, the tanner, the refuse-sorter literally spend their lives amid the most offensive odors and putrefying materials, and yet their mortality is scarcely perceptibly heightened thereby. The workers in our foundries, our smelters, and our engine-rooms live at terrific temperatures for hours at a stretch with comparative impunity. The Swansea copper smelter, for instance, works hard for seven or eight hours a day in a temperature of from 102°–110° Fahrenheit, exposed to a glare, when the doors are opened, of from 350° to 400°, drinking from two to three gallons of water a day to supply his loss by perspiration, and yet he is a hale, hearty fellow, and lives to a good old age.

In fact, man can accustom himself to work with safety and even comfort at almost any temperature, pressure, degree of moisture or dryness, in almost any position or atmosphere, providing he is reasonably well fed and housed, and maintains a fair general condition of health.

And it were well for our bacteriologic brethren, indeed, for all of us, to remember that the toughness and resisting-power of the human body are just as great against disease and all its germs as against any other unfavorable influence; that the fixed cells of our own bodies are to the deadliest bacilli as a regiment of British infantry to a swarm of Hottentots; that the hottest place a disease-germ can get into is a healthy bronchus or stomach.

Our chief aim in the cure of disease should ever be to "give Nature a chance."

NERVOUS DISEASES AND MODERN LIFE.

THE foregoing is the caption of a most interesting and brilliant contribution to the *Contemporary Review* by Dr. T. Clifford Allbutt, in which it is most cheering to find him vigorously opposing the prevailing impression that our nerves are going to rack and ruin under the strain of civilization. He first

points out that most of those who indulge themselves upon this subject are in the habit of arguing somewhat in a circle to the effect that, firstly, nervous diseases are on the increase, therefore modern life must be injurious, and secondly, that modern life is mischievous, therefore nervous maladies must be increasing.

The stock-in-trade argument in support of the first proposition is the alleged increase of insanity. This, Dr. Allbutt considers at some length, and concludes that the "figgers" are in reality misleading when certain other facts are taken into account. First of all, our lists of the insane are much more complete than they could be twenty years ago, and a very much larger proportion of them are cared for in asylums of some sort; the days of the village "innocent" or the household "deficient" are over. Second, the life-terms of these unfortunate creatures, no longer permitted to roam at large in all weathers and beg their food, protected against their own folly or violence and carefully nursed and treated in illness, have been greatly prolonged, so that a much larger number of them would be living at any given time. Indeed, from his own observation and his inquiries of experts Dr. Allbutt is inclined to believe that insanity is actually slightly on the decline, although apparently (from the causes named) on the increase. He further questions whether modern conditions are in any way responsible for the mass of our existing insanity. The greatest increase noticeable, for instance, comes from the agricultural laboring class, who are, of all others, least subject to the bustle, strain, and excitement of civilized life. No class or profession can be said to be more liable to insanity than any other; indeed, some of the highest percentages are to be found in the illiterate classes. History abundantly shows that possession by devils, frenzies, epidemic manias, etc., are and have been at least as common among savage tribes as similar mental disturbances among civilized peoples.

The doctor next takes up the question of the increase of nervous diseases generally. He shrewdly opens with the remark that it is commonly alleged of nearly all chronic diseases that they are on the increase nowadays, carcinoma, heart-disease, and gout, for instance. Much of this he regards as due to the simple fact that, to use a Hibernicism, "more people live to die of them." Our great advances in hygiene, dietetics, quarantine, and therapeutics have greatly decreased infant-mortality and the infection death-rate, which, of course, leaves a larger proportion of individuals surviving to adult or middle life subject to the diseases named, "for die we must somehow," as he quaintly remarks. Then, again, we are becoming much more attentive to symptoms of disease or discomfort than formerly, less inclined to resign ourselves to things, more determined to have a name and a cure for our ailments. The "patient invalid" of exemplary piety is no longer our ideal; but "our neurotics have begun, like ghosts, to walk, and we exclaim that the earth is full of them." As a result of this impatient resistance we are so much better fed, housed, exercised, and treated that the physique of all classes has been greatly improved, and particularly that of the upper and middle classes.

There is a delightful ring of sturdy sense in Dr. Allbutt's protest that most of the results attributed to "overwork" and "overstrain" are really due to the bad physical habits of the worker, and senseless methods in which the work is done, such as under-feeding or over-feeding, hurried eating, stuffy rooms, insufficient air, exercise, and recreation, etc., and not to the work itself. We are only just beginning to know *how to work* intelligently. Our medical courses, even their surroundings, are a disgrace to the age, and "business-methods" are even worse.

And now comes the most interesting position of the whole paper, and, in our judgment, the most impregnable: that the popular belief that because the greatest demands of the age fall upon the nervous system the latter is injured thereby is entirely fallacious. On the contrary, it is strengthened and invigorated by exercise, just as any other part of the organism. The whole life of civilized man is becoming so much wider and healthier and happier that his nervous system is becoming really stronger and better balanced every year. The nineteenth-century nerves are better able to bear the demands upon them than were those of the eighteenth century in their time. The age is better, broader, more humane, saner in every way, mentally, morally, and physically than it was a century ago. Such brutal coarseness and obscenity as Hogarth's pencil and Swift's pen sketched on every highway and parlor-carpet could hardly be found nowadays save in Whitechapel or Five Points. Insanity is a disease of the narrow, ignorant, untrained mind, rather than of the contrary. (Farmers' wives, for instance, in this country furnish the largest female quota.)

Of course, this great development has necessarily

been accompanied by a higher degree of nervous excitability. But, as Allbutt neatly puts it, "it is the business of nerves to be excitable." It is an essential part of their sensitiveness, of their fineness of organization, which alone makes all this progress possible. Fancy a poet, a violinist, a statesman, a general even, without sensitive nerves. Most of the "over-excitability" of which we complain is due to *under*-exercise instead of overwork, just as a mettlesome horse becomes absolutely uncontrollable if kept too much in the stable, and frets himself into a lather when harnessed, instead of settling down to work. Just give our wailing neurotics plenty of work of interest, of responsibility even, and their ailments and "nervousness" will in most cases disappear as by magic. Not only this, but the neurotic is often actually under-sensitive rather than the contrary, absolutely apathetic, if not mentally anesthetic, in many respects. Indeed his excitability is not seldom due to lack of inhibition of the first impulse by some balancing sensation and motive. He is unbalanced from a deficiency and not from an excess of "nerves."

As to the senseless claim that we are fast becoming "degenerates" (the pseudo-scientific equivalent of "cranks," and like it so charmingly applicable to anybody we do not happen to approve of) under the strain, and that most of our so-called "genius" is a mild form of insanity, our authority briefly but effectively remarks that its advocates appear to have little real knowledge and no clear idea of either genius or insanity, and, he might have added, of history, either, for with these charlatans it is the exception that proves their rule with a vengeance. "In the hands of these gentlemen a man of mark is not admitted into the ranks of genius unless he can show some claims to insanity; while on the other hand a streak of this malady insures for very dull dogs a welcome into the inner circle." And he closes this section with the pithy reflection, "I will not inquire where the malady may lie between the observer and the observed."

In short, most of our "nervousness" is really due to defective control, lack of sufficiently keen and powerful balancing impulses, to narrowness, feebleness, and one-sidedness of development, and insufficiency of work and demand, rather than to the opposite. Superficial sensitiveness is often due to absence of real depth and breadth of feeling, while through wider sympathy, deeper passion, and more vigorous exercise of all our powers come both health and, what is better, progress. "It is in the battle rather than in the fruits of victory that we find the precious extract that is the medicine for the malady of our generation."

EDITORIAL COMMENTS.

Medical Abuses in New York.—The medical profession of New York City appears to be awakening to a realization of some of the abuses of which medical men are made the victims. At a recent meeting of the New York County Medical Association attention was forcibly directed, among other things, to the discourtesy with which physicians are sometimes treated by the lay trustees of semi-public hospitals, and to the injustice to the members of the profession from the free treatment in the numerous dispensaries of persons able to pay for medical attendance, and the treatment in hospitals of patients of comfortable means and more, without charge for professional attendance. The frequency was pointed out with which attending physicians are merely dropped from the medical staff without a word of notice or explanation. A committee was appointed with instructions to meet during the summer to prepare a report and to propose suitable remedies. The abuses referred to have been frequently discussed in these columns, and we are glad to see them receive official cognizance by a powerful and representative medical body. Active agitation of the subject must result in good, and the necessary remedy would be easy of application in the hands of an organized and united medical profession.

Selections from Medical Journals.—Our sprightly and enterprising contemporary, *The Medical Fortnightly*, recently took occasion to say that THE MEDICAL NEWS in its Medical Progress "always prints a collection of extracts from English, French, and German medical publications—rarely one from an American journal." Conscious of both the inaccuracy of this statement and of the injustice of the imputation contained in it, we have analyzed our Medical Progress and Therapeutic Notes for the past thirteen weeks and find that of ninety-two abstracts twenty-three were prepared from American journals and proceedings of American medical societies and the remainder from English, German, Austrian, Swiss, and French. As a matter of fact, *all* of the abstracts in the issue of June 22 were from American publications. We trust the fealty of THE MEDICAL NEWS to the American medical profession is too well established and their community of interests too obvious to require defence from hasty and ill-considered statement.

The State Board of Veterinary Medical Examiners of Pennsylvania.—Act 55, approved May 16, 1895, provides for the establishment of a Board of Examiners to regulate the practice of veterinary medicine and surgery in the State of Pennsylvania. The Board is to consist of five members appointed by the Governor, who shall be graduates of recognized veterinary colleges and of at least five years' practice. This most commendable Act goes into force on the first Monday in September, 1895,

after which no one shall enter upon the practice of veterinary medicine and surgery unless he has been duly licensed and registered, and no licence will be granted until the applicant has submitted to a theoretic and practical examination, including the following subjects: Veterinary anatomy, surgery, practice of medicine, obstetrics, pathology, chemistry, veterinary diagnosis, materia medica, therapeutics, physiology, zootechnics, sanitary medicine, and meat-and-milk inspection. Heavy penalties are imposed for violation of the Act.

Sweat Bake shops.—In an investigation undertaken by the Women's Union, a society of women interested in the labor-movement, shops have been discovered where bread is baked under most filthy conditions. These shops are usually in cellars where vermin and rats are in abundance, and in which the bakers sleep when off duty. Such shops are not confined to any special district, but may be found all over the city.

Public opinion can do much in bringing about a change, both in this and sweat-shop clothing, by demanding cleanliness in the manufacture of such articles. We understand the Union is about to publish a list of bakeries where proper sanitary conditions are enforced; a label has also been adopted which will be a guarantee of well-made bread.

The Report of the Trial of Amick vs. Reeves.—A distinguished correspondent writes us, *apropos* of the editorial in THE MEDICAL NEWS of June 29th, that perhaps sufficient publicity was not given to the appeal for subscriptions to the fund for the purpose of publishing in pamphlet-form the report of the trial of Amick *vs.* Reeves at Chattanooga, Tenn. The appeal appeared both in the *Philadelphia Polyclinic* and THE MEDICAL NEWS of April 27th, and we hope that our recent remarks will meet with an unequivocal response. THE MEDICAL NEWS will be glad to receive and acknowledge subscriptions of fifty cents and over. We have received $1.00 from Dr. R. S. Wallace.

CORRESPONDENCE.

LEGAL PROTECTION OF PROFESSIONAL CONFIDENCES.

To the Editor of THE MEDICAL NEWS,

SIR: It will probably interest readers of THE MEDICAL NEWS to know the exact wording of a law passed by the Legislature of Pennsylvania at its last session and signed by the Governor on June 18th, which was meant to provide protection for physicians called as witnesses in civil suits against questions the answers to which would injure the good name of their patients.

Here is the text of the law:

"An Act to Prevent Physicians and Surgeons from Testifying in Civil Cases to Communications made to them by their Patients.

"SECTION 1. Be it enacted by the Senate and House of Representatives of the Commonwealth of Pennsylvania in general assembly met, and it is hereby enacted by the authority of the same, That no person authorized to practise (*sic*) physics (*sic*) or surgery shall be allowed in any civil case to disclose any information which he acquired in attending a patient in a professional capacity, and which was necessary to enable him to act in that capacity, which shall tend to blacken the character of the patient, without his consent."

The courts will probably construe this law in the sense in which it was intended. But this sense might have been much better expressed, as any shrewd lawyer could easily juggle with the new law so that its object would be wholly defeated; and, as it contains no penal clause, there is nothing to prevent a physician (if moved by malice or carelessness) from doing precisely what it forbids.

Medical men may note that the law affects the position of a witness in *civil* suits only, and that it does not leave the medical witness any choice, but (so far as it may be operative) *forbids* him from violating professional confidences. Just how far the courts will rely upon the judgment of a physician-witness who objects to a question on the ground that a particular answer, if given, would "tend to blacken the character" of his patient remains to be seen. Meanwhile this law is a movement toward an end long desired by medical men, and it is to be hoped that it may accomplish what has been desired.

Respectfully,

CHARLES W. DULLES.

DETERIORATION OF DIPHTHERIA-TOXIN.

To the Editor of THE MEDICAL NEWS,

SIR: In your issue of June 1, 1895, in a footnote on page 600 of Dr. Howard's article on the treatment of diphtheria with antitoxin, he refers to my test of the antitoxin and the finding of a strength of 60 antitoxin-units to the cubic centimeter. Since these tests were made the flask of toxin that was used has been found to have lost its toxic properties to a great extent. When this change took place I do not know, but if it took place after the strength of the toxin was ascertained and before the antitoxins were tested, it of course invalidates the experiments.

Aronson's antitoxin was tested at the same time and found to have a strength of 100 antitoxin-units to the cubic centimeter, as reported by Aronson. This would tend to show that the toxin lost its properties after the tests. The only other flask of antitoxin in the laboratory was ruined by the laboratory-janitor carelessly mistaking the bottle and pouring some waste ether into it. At present we have no diphtheria-cultures in the laboratory of sufficient virulence to make new toxin and check the test.

Very respectfully yours,

CLARENCE O. AREY.

PATHOLOGIC LABORATORY, WESTERN RESERVE UNIVERSITY, CLEVELAND, OHIO.

A CEREBELLAR TUMOR.

To the Editor of THE MEDICAL NEWS,

SIR: Some of those who read my paper on "Brain-Syphilis," published in THE MEDICAL NEWS, January 19, 1895, may be interested to learn the result of the autopsy in Case III, which revealed a tumor the size of a large English walnut, situated on the anterior border of the right cerebellar lobe and attached to it by a pedicle. Unfortunately no microscopic examination was made, so that it is unknown whether or not the growth was specific.

The diagnosis was partly right and partly wrong. It

was correct in locating a tumor at the base of the brain on the right side, but wrong in not recognizing the involvement of the cerebellum. It was thought at the time I saw the patient that the ataxia could be accounted for by the diplopia which was present. But the situation of the tumor adequately explains the symptoms.

From the practical standpoint, however, the belief that the tumor was inoperable was fully justified.

Yours respectfully, THEODORE DILLER.

WESTINGHOUSE BUILDING, PITTSBURG.

VERATRUM VIRIDE IN THE TREATMENT OF PUERPERAL ECLAMPSIA.

To the Editor of THE MEDICAL NEWS,

SIR: Mrs. S., a multipara, aged twenty years, was seized with convulsions at the commencement of labor and was in the midst of her sixth attack when I reached her. No examination of the urine was made. The patient was very edematous. The usual remedies were tried without improvement. The pulse was 140 and bounding. I gave, hypodermically, six drops of veratrum viride, diluted with a little water, every half-hour till the pulse was brought to normal, when the convulsions ceased. The os was fully dilated by this time and a living child was soon afterward born. The patient had no return of the convulsions. The only after-effect of the remedy was a very sick stomach, which soon wore off. I gave three doses of the remedy in all.

Respectfully, C. M. HYDE.

AUGUSTA, MISS.

SOCIETY PROCEEDINGS.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twenty-first Annual Meeting, Held at Boston, June 5, 6, and 7, 1895.

(Concluded from page 740.)

DR. CHARLES K. MILLS opened a discussion on the subject of

CORTICAL LOCALIZATION IN THE LIGHT OF RECENT RESEARCHES INTO THE MINUTE ANATOMY OF THE CORTEX.

He said that the different theories as to the separate cortical localization of movements and of cutaneous and muscular sensation, which had been the subjects of so much controversy, have again become prominent in the light of the researches founded upon the methods of Golgi, and particularly those made by Raymon y Cajal, Von Gehuchten, Schäfer, Andriezen, and others. Those who contend against the doctrine that the Rolandic cortex is a purely motor region believe that they have received additional support for their views. The varying hypotheses with reference to the functions of the cortex were reviewed. He held that, as shown by Forel and Nansen, we have been too long handicapped by prevailing ideas of cell-action and by theories of the parts played by the cell-bodies as originating centers. Impulses are transmitted and transferred by processes as well as by cell-bodies, and the function of the latter is chiefly trophic. The new researches and theories, he believed, did not compel abandonment of former views as to special localizations, although different standpoints had been taken. Disregarding theory entirely, he believed that the subdivision of the cerebrum into physiologic lobes—higher psychic, motor, sensory (meaning for the representation of cutaneous and muscular sensations), visual, auditory, olfactory, gustatory, and naming—remained for the practical purposes of the physician and surgeon the best; while the whole of the cortex in some of its strata may be regarded as a sensory expanse, if the Rolandic portions and particularly the convolutions cephalad of the central fissure constitute a region that is related to specialized movements of various parts of the body. One calls it motor, another kinesthetic, another sensorimotor, and another executive; but for the purposes of the physician and surgeon it is a motor sphere, the irritation of which causes specialized movements, while its destruction impairs or abolishes these movements. He did not believe with Andriezen that it is necessary to regard the ambiguous and great pyramidal cells of this region, whose apical processes received the terminals of the fillet-radiations, as the first sensory cells of the cortex. Indeed, he regarded it as important to rid ourselves entirely of the idea of sensory cells and motor cells. The cortex contains localized areas. To abandon separate sensory and motor localization would, he believed, necessitate the abandonment of visual, auditory, gustatory, and other subdivisions of the cortex. The cerebral sensory area—that is, the area of representation for skin-sensations and muscle-sensations, both cortical and subcortical—from his point of view, would be that part of the cerebrum where the fillet-radiations in their most compact forms are nearest to the surface of the brain, and therefore this region might continue to be described, as it had been by him, as in the postero-parietal, quadrate, and fornicate convolutions. Destruction of this region, especially if bilateral, caused more or less impairment of sensation. He referred to cases as confirming this view. In the cerebrum, as in the spinal cord, were fields of junction between so-called cortical areas, and lesions of these fields of conjunction or at the terminations of the sensory projection-fibers might give rise to temporary phenomena; but persistent sensory disturbances were found only when the lesions involved the convolutions included by him in the general sensory area.

DR. DANA said that he had collected a number of other cases, and added some of his own, and it is because he cannot explain the clinical facts or the pathologic facts by any other hypothesis than by supposing that the motor and sensory functions are practically united that he still holds to that view. He asked Dr. Mills to explain why, when one cuts away a section of the midcentral, precentral convolution, he finds tactile anesthesia and muscular anesthesia the next day, with paralysis, on any theory except that these two functions are united in that spot. These cases are extremely numerous in the literature of neurology. If one carefully shaves off the anterior, precentral convolution in the middle part, he will get sensory disturbances and anesthesia. Dr. Mills may not perhaps be aware that in the living subject the motor cortex has been directly irritated, also in front of the fissure of Rolando, producing sensory and motor disturbances. The whole weight of clinical evidence is in favor of this view—the surgical operations, the tumors, the softenings; all are

facts that cannot be explained on any other hypothesis so far as he knew than that the two functions are essentially identical anatomically.

It is a plausible theory that the visual centers, the center for visual sensation and auditory and gustatory sensations are separate from the motor sensations; these and cutaneous and muscular sensations would naturally have separate centers, but it does not at all hold against any actual facts; and when we come to analyze it, it is not so necessary or plausible after all. The visual sensations are not so closely related to motions as are the cutaneous and muscular sensations. For the performance of co-ordinated movement we must have a very close anatomic relationship between the muscular and cutaneous sensations. They must be close together anatomically for the purposes of a perfect machine, otherwise we could not make rapid motions; and he believed it is for that reason that nature had gradually shifted the sensory receptive cells so that they are in approximately close relations with the motor cells. He believed that perhaps if we were all agreed as to exactly what is meant by sensations, and exactly what tests we use for making sensations, and were agreed about the terminology of our discussions, we would not perhaps have so much discussion about this matter. He agreed with Dr. Mills that sensations are not closely localized, and he agreed that we should speak of sensory areas, but did not believe that we have sensory areas separate from the motor ones back in the post-central and parietal lobes or in the gyrus fornicatus. He does not accept Dr. Starr's view that the sensory centers are back of the fissure of Rolando, for, from the evidence that he has been able to collect, there is just as much proof that the precentral convolution has sensory functions as that the post-central one has.

DR. PUTNAM thought Dr. Dana's closing sentence must be accepted as absolutely certain, that the convolution in advance of the fissure of Rolando, which we ordinarily associate with the localized movements, has as much to do with sensation as convolutions anywhere else. In support of that fact he mentioned one case among many in which Dr. Warren excised a minute piece of the cortex of a young man with epilepsy beginning in one hand—a piece a few millimeters in diameter—with the result of producing paresis of the hand, paralysis in the beginning, and also a disturbance of the sensibility of the whole hand. It seemed to him that this showed that in some way the function of sensibility is closely related to the same centers with the function of motion. We are still decidedly lacking in a sufficiently adequate physiologic or psychologic conception of what we mean by these various terms. The function of sensibility must be very widely distributed.

For example, an enormous tumor was removed, almost as large as an orange, which lay directly in the motor tract, so that the whole of the motor area was removed with a good part of the internal capsule. Nevertheless that patient still has a very considerable degree of sensation left, of course modified, but he feels in a very high degree, so that although the removal of the motor convolution has affected the sensibility of the limb it has not by any manner of means destroyed it. Nerves will stand a high degree of injury, sufficient to destroy entirely their motor functions, without material interference with their sensory functions. The same thing is true as to the cord; a minute portion of it will convey centripetal impressions.

Although we must admit that the function of sensibility is closely related to the function of localized motion, we must admit that it is closely related to a great many other functions, and it remains to be seen whether, as in the case of the relation of the muscles of articulation to the function of speech, there is any center that is highly specialized. He had in mind several cases in which the sensory functions have been disturbed in connection with paresis of one hand, in which he seemed to be able to detect a greater degree of loss of sensibility or impairment of sensibility on the side of the ulnar part of the hand on the median portion.

DR. STARR said we certainly have facts that Dr. Dana has stated that are indisputable, and those who are constantly seeing cases of cerebral surgery and excecting cysts and portions of the cortex by clots that can be removed are perfectly positive that a small limited area of the so-called motor zone does inevitably produce in almost every case more or less disturbance of sensation. He said he was completely mistaken in 1890, when he maintained that sensations were only to be referred behind the fissure of Rolando. He believed with Dr. Dana completely to-day that there are sensations produced by small lesions anterior to the fissure of Rolando, and that the sensory area of the body corresponds exactly with the motor area of the body so far as we can determine clinically. He thought it would be a mistake to draw too broad a conclusion from these facts.

It is perfectly evident that the term diffusion of sensibility is a capital one, and our present anatomy shows why it is; it is because the sensory fibers terminate in brush-like expansions, so that we must conceive of a sensory fiber as virtually terminating in a long region of the nervous system; in fact, almost throughout its entire length. Now suppose that with the continued passage of sensations over these fibers diffusing themselves in general directions habit opens the way in one direction rather than in another, that a sensation coming in might be diffused from the arm over the entire parietal arm-center and also diffused over the motor center, but inasmuch as we guide our movements by touch habitually the result is that a greater passage is opened out to the motor zone. Diffusion of the sensibility in various areas gives an explanation for the fact that a few cases are on record in which we get sensation lost alone, and the vast majority of cases show that sensation and motion are lost together. We must abandon the idea that consciousness and conscious perception, and perhaps to some extent conscious motion, are associated with the particular cells. It is just as reasonable to believe that they are associated by association fiber-action with the combined activity of various areas of the brain as they are with single cells, and he thought we will come down finally to the fact that a cell is to be regarded more as a trophic center than as a motor or sensory center.

DR. DERCUM said that the stand that had been taken enables us to explain certain other phenomena not alluded to here, namely, the fact that the cuneus atrophies in cases of blindness lasting for many years. Certain it is that we have no right to conclude from these facts that the cuneus only sees. It is probable it does

other things. The various centers of the cortex, as we know them clinically and pathologically, are simply highways of ingress and egress to the general cortex. It gives us no right to say that this portion of the brain may do this special thing and that portion that special thing. General biologic considerations also would negative the sharp differentiation of cells into special functions. Nerve-protoplasm reacts to certain forces; to say one cell would react to one mode of motion and another to another is unphilosophic and not borne out by general biologic considerations.

DR. RICHARDSON said, in reference to the tumor of which Dr. Putnam spoke, that so far as he knew there was no destruction of the motor areas except by pressure of the growth. The tumor was very large. It took up a very large portion of the left hemisphere. But so far as he knew, there was no destruction of brain-tissue by manipulation during the operation. The man is now doing very well.

DR. COLLINS recently had a case of cerebral surgery in which the development of sensory and motor defects was rather peculiar. The young man had had his first attack of Jacksonian epilepsy in November, and the movements were contraction of the finger and thumb. When he saw him in March he had had three seizures. In conjunction with Dr. Sachs, Dr. Gerster operated on the patient over the superficial cortical thumb-and-index-finger center. As the patient bore the anesthetic very badly, it was necessary to postpone the operation after the skull had been opened; that is, cutting into the cortex was deferred. That night he had an extremely severe attack, which had been preceded a short time by a very high temperature and loss of consciousness for a long time. The following morning he had paresis of the right upper extremity and loss of sensation; that is, loss of tactile sense, loss of sense of position, and loss of muscular sense in the right hand. Three or four days afterward the dressings were opened and a good deal of distention was found from effusion into the surrounding cellular tissue, but otherwise where the operation had been done it seemed very much like normal. Then a large part of the cortex was cut out. An old pachymeningitis was present, and the Nissl stain revealed degeneration of the cortical cells. He was put to bed and his hand tested for sensibility that evening. The disturbances of sensation had all disappeared. These observations were made with extreme care.

DR. ANGELL, of Rochester, corroborated Dr. Collins because he had had a similar case. He made the prediction that there would be paralysis for five or six days at least, and to his surprise, when the boy recovered from the ether two or three hours after the operation, he tested him thoroughly and found sensory paralysis. Within twenty-four hours there was absolutely no sensory paralysis or sensory disturbance. He did not believe it possible to make an impression upon any center of the brain closely related to another center without affecting temporarily that sensory center. Whether or not this will explain the reason why we have a short paralysis of sensation when we remove the motor cortex is, of course, beyond our power yet to determine. It may be by cutting into the cortex that we affect the rootlets of the radicles from the sensory tract which we suppose reach over and produce this diffusion of sensation that has been referred to.

DR. PRINCE, of Boston, said there is a third fact that Dr. Starr had left out of consideration, and that is the fact that in many cases which had been referred to by other gentlemen there had been no loss of sensation. These must be exceptional cases that must be taken into consideration in order to find a law. A great many could be mentioned. He referred to two which he thought were of great importance. In one case he first scooped out a piece of the brain equal in size to half an orange, leaving a hole two inches in depth, involving a very large portion of the upper part of the descending convolutions, caudate lobule, and some part of the parietal convolution. Before the operation there was hemianesthesia with paralysis; after operation there was absolutely no loss of sensation whatsoever tested in the most minute way. A case like that, it seemed to him, is a crucial case, and if the word center has any meaning whatsoever it must mean a portion of brain the function of which is destroyed when taken away.

These cases show that a large portion of the motor cortex can be destroyed without loss of sensation.

DR. PUTNAM, of Boston, said that no one would speak clinically or anatomically of the sense of hearing and comprehension of spoken words as located in the same part of the brain, but we know that these two functions lean on each other internally so closely that not only do we get more or less aphasia from disturbance of the center for hearing, but we also get to a less degree a great deal, as is also the case with sensory phenomena, of disturbance of centers of comprehension in most forms of motor aphasia. In short, cerebral functions do not exist in themselves; they exist as related to other functions, and one cannot destroy one without more or less impairing others, although it may be only for a brief time.

THE PRESIDENT added that the whole of our knowledge of the neuron goes to show the very pronounced dependence of the motor neuron upon the sensory neuron. In the primary neurons it has been clearly proved that the terminal processes of the axis-cylinder of the sensory neuron are closely connected with the apical process of the motor neuron in the cord. The development of fibers in the cortex, in the brain itself, shows that the sensory tract passes distinctly upward toward the central convolution, the parietal region, rather than downward and inward toward the gyrus fornicatus, where Ferrier some time ago located the sensory centers, and where Dr. Mills still has a leaning toward placing it. In other words, judging from all the analogies in the anatomy of the brain, the higher sensory neurons must either pass upward directly to connect by their axis-cylinder processes with the cells of the motor neuron, or there must be association-tracts from these axis-cylinders going up to the motor processes. We find no association-tract passing up from the gyrus fornicatus to the central fissures; and, furthermore, although Dr. Prince had just brought up the negative cases of lesion of the central convolution without injury to sensation, there have been in the past a very large number of so-called negative cases about the central convolution with absolutely no motor disturbance. Most of those, with our increasing knowledge, have been explained away, and ten negative cases do not afford as much evidence as one positive case. The positive cases of sensory disturbances following lesions behind and in front of the

fissure of Rolando are increasing in number and become very conclusive. The positive cases of lesion in the neighborhood of the gyrus fornicatus are very few and far between.

DR. MILLS, in closing, claimed that this discussion confirmed the standpoints he had always taken. It seemed to him astounding that Dr. Dana and others here speak of the cases in which physiologic or pathologic lesion of the motor cortex as exceptionally producing alone motor symptoms. Every one of us must admit the cases referred to by Dr. Starr and Dr. Dana, and by Dr. Putnam and Dr. Knapp's case, because we know they have been well studied and well recorded; that is, cases in which sensory phenomena of some sort have accompanied the motor phenomena in cases of destructive lesion of the pre-Rolandic cortex. We must also admit the two or three cases in which certain experiments upon the cortex in life have caused peculiar temporary disturbances of sensation at the time. These cases of sensory disturbance from strictly limited lesion of the motor cortex, cases in which the symptoms were motor alone instead of sensory, are as one-hundred to one, and we do not think it longer worth while to collect these cases. In a score of these cases the patients have been examined in life with the greatest care and the lesions located in death, and in cases of operation the greatest care had been taken in studying sensory phenomena, and those sensory phenomena had not been present. He mentioned two cases in which the motor phenomena persisted day after day, and day after day changes were noted until the patient was largely restored as regards motion, sensation not having disappeared at all. He did not think it worth while, therefore, to pit these cases which Dr. Dana had collected as an argument of great value against the very numerous cases that teach the other thing. However, he must acknowledge the other cases. Have we no explanation for these cases? He would suggest three or four explanations for these cases in which destructive lesions cephalad of the sensory area have given rise to sensory disturbance. One explanation, which may seem far-fetched, is that these cases are somewhat of the nature of the cases in which we have sensory disturbances in hystero-traumatisms. Certainly the traumatism inflicted by the surgeon's knife, or by injury or disease, in acute cases, or by operation such as Dr. Dana refers to, is greater than that which we have in these other cases. Another explanation is that he suggested in 1888, and which grows out of these later researches on cortex anatomy. Undoubtedly every area of the cortex, visual, auditory, gustatory, sensory, etc., must be related to and anatomically connected with the motor regions of the cortex. Now it is through the destruction of these terminals of the fillet-radiations, whether they be continuous with the apical process of the pyramidal cells or simply constitute a field of conjunction, we have a separation between the motor and sensory areas, and at least temporary disturbances of sensation would very likely in many instances result. It is a great cortical sensory expanse in this sense, but there is one region in the brain in which these fillet-radiations are placed between the cortex, and which for the surgeon's and physician's purpose should be regarded as the sensory region. It is next to the motor region and between the motor and great sensory region. It has a separation, and one which is practical for our purposes.

The remarks made by Dr. Starr, he thought, were on the whole confirmatory of what he had stated. It would seem, therefore, that the weight of argument and the weight of the evidence advanced here are still in favor of the localizations to which he had always clung, and which were believed in by Charcot, Ferrier, and others. He had never claimed that the gyrus fornicatus was the sole region of common sensibility in the cortex of the brain. His own position has always been that the sensory cortex proper includes at least a portion of the gyrus fornicatus, the quadrate lobule, and the posterior parietal convolutions, and the arguments he advances must stand for the motor region, and not for a part of it.

DR. DANA asked if Dr. Mills would state specifically whether he denies that the central convolutions have any sensory function; if he absolutely excludes sensory function from the central convolution.

DR. MILLS replied that for our purposes and for our practical idea of a center or area he believed the central convolution or convolution cephalad of the central fissure had no sensory function; he believed the posterior central convolution and the posterior parietal and the region he had named perhaps take part in sensory phenomena, that is, the sensory region posterior to the central fissure.

TUMOR OF CEREBELLUM, WITH AUTOPSY,

was the title of a paper read by DR. E. D. FISHER, of New York. The interesting features of the case were the absence of any symptoms that could be directly referred to the cerebellum. There was no inco-ordination —nor any staggering in the gait. The pain was situated principally over the right orbit. The only well-defined cranial lesion was that of the eighth nerve on the right side, there being absolute deafness. There was possibly a slight involvement of the seventh nerve on the right side, and the patient said she had complete loss of smell. The general symptoms of a cerebral tumor—*i. e.*, headache, convulsion, and optic neuritis—were present. A lesion at the base of the brain was suggested by the cranial nerve lesion, with involvement of the cerebellum; the absence, however, of cerebellar symptoms and the localization of the pain so definitely over the right orbit led to an exploratory operation in that situation. The tumor was not found at the time, but there was a complete relief from the pain and the convulsions until the time of death, eleven weeks later, which was caused by a septic basilar meningitis. Autopsy revealed a glioma involving the right cerebellar hemisphere.

DR. PRESTON, of Baltimore, related

THREE CASES OF TUMOR OF THE BRAIN, WITH AUTOPSY.

The first case was that of a boy, aged thirteen years. For a year he had what looked like ordinary epileptic attacks, which were very much lessened by the bromids. Then he suddenly developed diplopia, with some neuro-retinitis. Vision was greatly reduced, and there was at first left lateral achromatopsia, and afterward left hemianopsia. Gradually he lost entirely both sight and hearing. The reflexes, both superficial and deep, were lost. He complained of most intense headache, and there was gradual failure of mental power. The autopsy revealed a large tumor, involving the entire right temporal lobe; the occipital lobe was softened and broken

down, but the cortical portion of the occipital lobe was not involved. The tumor was a sarcoma. The second case was interesting from the fact that the tumor, a small papilloma, not larger than a partridge-egg, burying itself in the right superior occipital convolution, produced intense headache, with double optic neuritis. The third case showed a large sarcomatous tumor involving the temporal lobe, all except the first convolution, the greater part of the occipital lobe, and the lateral lobe of the cerebellum. The symptoms were not very well marked, except headache and mental disturbance. It was interesting to note that the first temporal convolution was not involved, though the rest of the lobe was virtually destroyed, and in accordance with our accepted views concerning the auditory center there was deafness.

A specimen of

BRAIN-TUMOR

was presented by DR. G. L. WALTON, of Boston. The main interest was the question whether an operation might have proved successful. The patient was fifty-three years of age, and complained of frontal headache only two months before his death. Attacks of vertigo, loss of speech, and severe general convulsions preceded and followed. Aphasia, agraphia, right hemiplegia, and right hemianopsia were present, with double optic neuritis and loss of superficial reflexes on the right. The tumor occupied the angle between the Rolandic and Sylvian fissures. Extension forward under the healthy cortex reached beyond the transverse frontal sulcus. It was fairly well defined, but with no distinct capsule. The center was necrotic. The symptoms suggested so extensive infiltration that operation was considered to offer small hope, but the extension backward was not so great as the hemianopsia would indicate, a fact which, together with recently published cases of removal of large infiltrating gliomata, would lead, perhaps, to a somewhat more hopeful prognosis in another case of this nature.

The three preceding papers were discussed together.

DR. STARR referred to a case of infiltrating glioma in the arm-area of the motor zone. Symptoms developed in the course of a year: Headache, optic neuritis, spasm of the right hand and arm, and later paresis and loss of sensation. Operation revealed a glioma, very extensive and very vascular. It was impossible to remove it safely. Death followed within a few hours. He mentioned a case of suspected tumor of the corpora quadrigemina. A flap of bone was removed from the parietal region, and an attempt to puncture the ventricles was unsuccessful. There was no relief of pain. He concluded that operation under such conditions was useless. He agreed with Dr. Fisher that the position of pain is of no value in localization.

DR. DANA said that the use of the chisel upon children and infants is a bad method of operation. He recommended the use of the improved revolving electric saw, as used by Dr. Powell, of New York.

DR. GEORGE W. JACOBY, of New York, had witnessed two operations upon adults in which the electric saw was used. He considered the method objectionable, as there was more hemorrhage, and a wedging of the saw interfered with the operation. He spoke favorably of Quincke's lumbar puncture for relief of intracranial pressure.

DR. DERCUM spoke in favor of a perpendicular burr worked by a dental engine.

DR. COLLINS had seen a case in which, after each series of blows from the mallet and chisel, the pulse fell from 60 or 70 to 35 or 40.

DR. G. M. HAMMOND had witnessed one operation with the electric saw upon an adult and many upon children. The saw as now used has a greater electromotive force to operate it than formerly, and this obviates the earlier difficulties as mentioned by Dr. Jacoby.

DR. DERCUM had noticed the same symptoms following the use of the chisel as described by Dr. Collins.

A case of

INJURY OF THE ANGULAR GYRUS FROM FRACTURE OF THE SKULL

was reported by DR. C. EUGENE RIGGS, of St. Paul.

HEREDITARY CHOREA, WITH AUTOPSY,

was the title of a paper by DR. CHARLES L. DANA, of New York.

DR. MILLS looked upon the case as very important. It suggested the true explanation of a large class of cases (such as Friedreich's ataxia, hereditary chorea, spastic paralysis), that these are teratologic.

DR. H. A. TOMLINSON, of St. Peter, read a paper on

INSANITY AND PHTHISIS, THEIR TRANSMUTATION, CONCURRENCE, AND COEXISTENCE.

He considered that pulmonary tuberculosis and insanity are equally potent factors in the production of brain-instability. The preponderance of degeneration among those having an heredity of tuberculosis is significant, as indicative of the influence of this disease in one generation, in determining a defective nervous system in the next, and his tables also indicated that the more direct the heredity the greater is the probability of transmutation. Disease-processes which are constitutional or diathetic attack primarily one or other form of tissue, with the result of progressive degeneration and disintegration if the tissue be epithelial. However, if the connective tissue is the seat of a disease-process, it either increases rapidly in amount, and remains permanently increased, or undergoes liquefaction.

The most common form of degeneration among the insane is the connective-tissue type, or the premature and excessive manifestation of the changes which ordinarily occur in senility. The preponderance of imperfectly developed connective tissue in one generation implies the excessive development of functional tissue in the next, thus accounting for the transmutation of disease-tendency. These changes are abundantly illustrated in the tuberculous and defective children of neurotic or syphilitic parents.

THIRD DAY—JUNE 7TH.

DR. WM. N. BULLARD, of Boston, read a paper on

THE DIAGNOSIS OF PACHYMENINGITIS INTERNA HÆMORRHAGICA.

He considered the pathology of this affection as yet unsettled, though he believed the weight of evidence to be in favor of a non-inflammatory origin. There are several forms of subdural hemorrhage, but consideration was given only to the apparently spontaneous, non-traumatic

affection occurring in aqults. The points of differential diagnosis between this condition and other forms of intracranial hemorrhage are as follows: (1) subdural hemorrhage is peculiarly common in paralytic dements and in the chronic insane, and not rare in chronic alcoholics; (2) the onset is often more gradual than in ordinary intracranial hemorrhage, and the irritative stage lasts unusually long; (3) the symptoms of irritation are prominent. General epileptiform convulsions and localized convulsive movements are likely to occur. (4) The peculiar rigidity occurring in one limb in connection with symptoms of hemorrhage, and when no affection like tuberculous meningitis exists, is very significant. The treatment in this condition is removal of the clot. In all more serious cases this should be done as soon as the disease is recognized. A case was reported in which operation was performed and the clot removed, although too late to save the life of the patient.

DR. TOMLINSON thought the term pachymeningitis a misnomer. The primary condition is non-inflammatory. In syphilitic cases there are no signs of active inflammation, but changes in the bloodvessels.

DR. FISHER believed that the blood comes from newly formed vessels which have resulted from inflammation, and asked what the special indications were for operative interference.

DR. BULLARD answered that operation was indicated when symptoms of pressure existed. The question as to the origin of the disease remains *sub judice*.

DR. E. W. TAYLOR, of Boston, presented a case of

TABES AND MULTIPLE SCLEROSIS.

There had been probable syphilitic infection twenty years before. The patient first noticed a tremor of the hands fourteen years ago, followed by pain of a lancinating character in the legs, associated with general muscular weakness. There were gradual increase of these symptoms, with occasional paresthesia of the legs; girdle-sensation and difficulty in micturition; loss of knee-jerk; Argyll-Robertson pupil; lancinating pains; disturbances of sensibility; so that the diagnosis of tabes dorsalis was unquestioned. In addition there were slight nystagmus, spasm of the posterior thigh-muscles, muscular weakness, hesitating speech, and absolutely characteristic intention-tremor masking the little ataxia present.

DR. PRINCE then presented microscopic specimens from a case of

CEREBRO-SPINAL SYPHILIS.

DR. JOSEPH COLLINS, of New York, read a paper on the

PATHOLOGY AND MORBID ANATOMY OF AMYOTROPHIC LATERAL SCLEROSIS.

He referred to the moderately constant clinical picture of amyotrophic lateral sclerosis, and the variable pathologic conditions on which it has been found to be dependent, and pointed out that the number of cases in the literature that were well substantiated by autopsy were fewer than one might be inclined to think. Reference was also made to the different views held by the followers of Charcot and Erb on one hand, and of Gowers, Leyden, and others on the other hand, as to whether the disease is primarily of the pyramids, with secondary involvement of the anterior horns, or whether it is but a variation of the common form of progressive muscular atrophy. The case was reported of a man, thirty-three years of age, in which after death atrophy of the ganglionic cells throughout the cord was found, Throughout the cord, but especially in the cervical and dorsal regions, there were evidences of excessive vascularity, in the shape of large, thickened bloodvessels, especially in the gray matter, and there were spaces from which the vessels had disappeared. In the cervical cord, corresponding to the place of apparent softening in the recent state, was found great disorganization of the ground-substance of the anterior horns. In the medulla there was degeneration of the nuclei throughout the entire extent, with the exception of the extreme caudal end. There was also slight degeneration in the tenth and common vago-accessorio-glosso-pharyngeal nucleus, but none in the pyramids of the medulla. The root of the twelfth nerve was small and delicate. A second case occurred in a male, forty-eight years of age. Cultures made from a piece of cord from the cervical region revealed the presence of the tubercle-bacillus in considerable numbers. In the cervical region there was degeneration in the crossed and direct pyramidal tracts, with almost complete destruction of the anterior horns. In the dorsal region there were sclerosis of the crossed pyramidal tracts, slight sclerosis of the ascending cerebellar tract, diffusedly distributed dilated bloodvessels, some with very much thickened walls; extensive atrophy of the cells of the anterior horns, some degeneration of the lumbar and sacral regions, and in the dorsal, but in less degree. In the medulla atrophic changes were found in the nucleus of the twelfth nerve. A hemorrhage of ancient date was present in the dorsal region.

DR. WILLIAM C. KRAUSS, of Buffalo, read a communication entitled

PERONEAL MUSCULAR ATROPHY, WITH AUTOPSY.

He reported the case of a man, seventy-eight years of age, who, at the age of eighteen, began to notice a weakness of the leg-muscles. This weakness was accompanied by atrophy in the peroneal and hamstring muscles of both legs and extended to the muscles of the thigh, the left thigh being much more affected than the right. Double club-foot of the *pes varus* variety resulted, and also a double *genu valgum*. The tendon-reflexes were absent on the left side, and also on the right, with the exception of the knee-jerk. Fibrillary contractions and sensory disturbances were entirely wanting. There were present lordosis and scoliosis of the lumbo-sacral region. The muscles of the upper extremities were unaffected. The patient gave no history of any infantile disease or of poliomyelitis, and ascribed the affection to an accident. The patient died from uremia. Microscopic examination of the spinal cord revealed atrophy of the anterior horns, especially on the left side, extending from the caudal part of the thoracic region to the conus medullaris. The multipolar cells of the antero-lateral group were visibly affected, in places having disappeared, in others undergone atrophy or degeneration, while the median group was less affected. The white matter was somewhat sclerosed, particularly in the antero-lateral and posterior columns, but not more than the age of the patient would warrant.

DR. COLLINS remarked that unless Dr. Krauss establishes that this was not a case of chronic anterior poliomyelitis, then it should not be accepted as one of the peroneal type of muscular atrophy.

DR. J. W. PUTNAM, of Buffalo, reported a case of

WRITER'S CRAMP

in a telegrapher. The man had previously had telegrapher's paralysis of the wrist, but later the symptoms increased to such an extent that the mere suggestion of writing, or the thought of writing, would bring on the spasm. This involved, in addition to the arm-muscles, the trapezius and the sterno-mastoid of the left side. The result was that, in attempting to write, the head would twist round to such an extent that the man was unable to see the paper. The patient was treated by hypnotism and deep muscular injections of atropin, with complete recovery after the lapse of two months.

DR. RIGGS related that he had seen a similar case, but that the trapezius was not involved. Much relief was obtained from the use of hyoscin hydrobromate.

DR. LESZYNSKY asked whether the favorable result was due to hypnotism or to atropin.

DR. PUTNAM replied that he attributed the recovery to suggestion through hypnotism.

DR. SMITH BAKER said that he had come to consider the associated contractions (those of the shoulder, head, etc.) as natural outcomes of the habitual attitude assumed by everyone whenever they intend to do any particular thing whatever. They may be designated as associated intention-contractions. The origin of these undoubtedly dates back to the time of either learning to write or of some position incidentally assumed for comfort, or other favoring result. The cure may come about through any means whereby the associations are broken up. Possibly writer's cramp itself is most frequently of purely psychic origin, and so rest, or hypnotism, or any other efficient psychic impression kept up long enough will result in recovery.

DR. SMITH BAKER, of Utica, read a paper on

AUTOMIMESIS,

which he defined as the process whereby impressions from the outside world or conceptions arising in the mind are first set as copy-models, and then automatically reproduced more or less indefinitely, until results detrimental or otherwise are attained. As usually considered, imitation means the reproduction of features found in other individuals. Automimesis or self-mimicry means the serial reproduction of characteristics dominant at some particular time in one's own mind. How such a copy-model first comes to be set and subsequently followed is often a mystery, but a pain, or shock, or word, or muscular tension, or unusual idea, or any incidental experience undoubtedly affords the requisite suggestion—imitative impulse. This is often seen in the development of hysteria, neurasthenia, melancholia, insistent ideation and allied states and tendencies, while evidence is accumulating to show that the succeeding automimetic series is a quite natural outcome of such an imitative impression. Cases illustrating automimetic development of disease were given, and the conclusion reached that possibly in this way there have been opened up points of view both as to etiology and therapy which are of value to neurologists.

DR. RALPH L. PARSONS, of Sing Sing, presented drawings and photographs illustrative of a new system of baths inaugurated at the institution with which he is connected.

DR. G. L. WALTON, of Boston, read a paper on

OBSTETRIC PARALYSIS.

He said that it is assumed that this condition is due to a stretching of the brachial plexus at a spot above the origin of the supra-scapular nerve. This does not account for the escape of the branch to the pectoralis major, which passes off immediately below. The same difficulty presents itself in the theory of pressure against the clavicle. It was suggested that the supra-scapular nerve is probably bruised independently against the supra-scapular notch or spine of the scapula, while the plexus below is bruised against the clavicle. The branch to the pectoralis major escapes through having no bony point of fixation. Probably rotation of the face away from the shoulder that is caught at the brim of the pelvis aids the stretching, as well as the drawing away of the head, already described in this connection.

The following papers were read by title: "Home-treatment of Insanity," by Dr. H. M. Bannister, of Chicago; "The Dual Action of the Brain," by Dr. Samuel B. Lyon, of Bloomingdale; "An Operative Procedure for the Relief of Basilar Meningitis Limited to the Posterior Fossa," by Dr. J. T. Eskridge, of Denver; "Fissural Studies of the Brain of Two Philosophers," by Dr. Burt G. Wilder, of Ithaca; "The Association of Tabes and Paretic Dementia," by Dr. Theodore Diller, of Pittsburg; "Must Acute Paranoia be Admitted into Our Nomenclature?" by Dr. William Noyes, of Foxboro; "The Conservative Value of the Play-impulse," by Dr. Irving G. Rosse, of Washington; "Telegrapher's Paralysis," by Dr. James Hendrie Lloyd, of Philadelphia; "Case of Multiple Neuritis in an Infant," by Dr. Graeme M. Hammond, of New York; "Pseudo-neurasthenia," by Dr. Morton Prince, of Boston.

The following were elected to active membership: Dr. Hugh F. Patrick, of Chicago; Dr. Edward Wyllys Taylor, of Boston; Dr. Leopold Stieglitz, of New York; Dr. John Jenks Thomas, of Boston; Dr. H. L. Worcester, of Danvers; Dr. B. Onuf, of Brooklyn, N. Y.; the following were elected to honorary membership: Dr. S. Weir Mitchell, of Philadelphia; Dr. Camillo Golgi; Dr. L. Edinger; of Frankfort; Dr. Ramon y Cajal, of Barcelona; Dr. Dejérine, of Paris.

The following officers were elected for the ensuing year: *President*, Dr. F. X. Dercum, of Philadelphia; *Vice-Presidents*, Dr. George J. Preston, of Baltimore, and Dr. C. E. Riggs, of St. Paul; *Secretary and Treasurer*, Dr. G. M. Hammond, of New York.

NEWS ITEMS.

The American Orthopedic Association will hold its ninth annual meeting at Chicago, September 17, 18, and 19, 1895. The following papers have already been promised: On Forcible Correction, and Corrective Jackets, in the Treatment of Scoliosis, by Dr. Barnard Bartow, of Buffalo; Idiopathic Osteoarthrosis, by Dr. Wallace Blanchard, of Chicago; (1) The Use of the Plaster Jacket in Caries and the Effect of Position on the Spine. (2)

Caries in Adults, by Dr. E. G. Brackett, of Boston; (1) Operative Measures in Caries of the Spine. (2) Treatment of Slipping Patella, by Dr. E. H. Bradford, of Boston; On the Surgical Treatment of Congenital Dislocations, by Mr. Bernard Brodhurst, of London, Eng.; Some Cases of Osteoclasis with the Lorenz Osteoclast, by Dr. F. S. Coolidge, of Chicago; Improved Osteoclast, by Dr. Nicholas Grattan, of Cork, Ireland; title not announced, Dr. V. P. Gibney, of New York; New (anterior) Spine Brace, with Exhibition of Patients, by Dr. A. E. Hoadley, of Chicago; title not announced, Dr. A. B. Hosmer, of Chicago; The Deformity of Hip-disease, by Dr. A. B. Judson, of New York; The Causative Relation of Suppuration to Tuberculous Meningitis in Joint and Spine Disease, by Dr. Samuel Ketch, of New York; Ambulatory Treatment of Pott's Disease, by Dr. R. W. Lovett, of Boston; Club-foot, by Dr. R. W. Lovett and Dr. John Dane, of Boston; (1) Congenital Absence of Radii, with Operation. (2) Exhibition of Hip-joint Brace. (3) Plaster-of-Paris in Orthopedic Surgery. (4) Specimens of Tuberculous Bone-disease, by Dr. S. L. McCurdy, of Pittsburg; (1) The Rawhide Corset Spinal Brace. (2) A Review of the Treatment of Hip-disease, by Dr. B. E. McKenzie, of Toronto; Spasmodic Wry-neck, by Dr. T. H. Myers, of New York; title not announced, Dr. C. B. Packard, of Denver; The Deformities Produced by Acute Inflammatory Lesions in Bone, by Dr. Roswell Park, of Buffalo; (1) The Report of a Case of Congenital Dislocation of the Shoulder, and an Operation for its Relief. (2) The Treatment of Fracture from an Orthopedic Standpoint. (3) How the Orthopedic Surgeon Should Treat Abscesses (tuberculous and purulent), by Dr. A. M. Phelps, of New York; The President's Address, by Dr. John Ridlon, of Chicago; One-thousand Cases of Lateral Curvature of the Spine Treated by Posture and Exercise, by Dr. Bernard Roth, of London, Eng.; The Anterior Spine-brace, by Dr. J. C. Schapps, of Brooklyn; Some Considerations of the Mechanical Arrangements Around the Hip-joint, by Dr. H. M. Sherman, of San Francisco; several papers, titles not announced, Mr. Noble Smith, of London, Eng.; A Case of Double Congenital Knee-luxation, by Dr. H. L. Taylor, of New York; (1) Pain in the Back. (2) Metatarsalgia. (3) The Use of Mechanical Support in the Treatment of Scoliosis, by Dr. L. A. Weigel, of Rochester; Observations on Weak-foot, with particular reference to its Predisposing Cause, its Diagnosis, and its Cure, by Dr. Royal Whitman, of New York; A Report of Seventy Cases of Splicing of the Tendo-Achillis, by Dr. H. Aug. Wilson, of Philadelphia; The Treatment of Scoliosis by Light Gymnastic Exercises, by Dr. J. K. Young, of Philadelphia.

Papers have also been promised, if there is time for their reading, by Drs. L. L. McArthur, Weller Van Hook, Robert Tilly, Joseph Zeisler, H. P. Woley, and other gentlemen of Chicago, but these papers will not be presented except by vote of the Association.

The Colorado State Medical Society held its twenty-fifth annual convention in Denver, June 18th, 19th, and 20th, and elected the following officers for the ensuing year: *President*, Dr. I. B. Perkins, of Denver; *First Vice-President*, Dr. A. J. Robinson, of Aspen; *Second Vice-President*, Dr. Lee Kahn, of Leadville; *Third Vice-President*, Dr. Mary Ambrook, of Boulder; *Corresponding Secretary*, Dr. E. R. Axtell, of Denver; *Recording Secretary*, Dr. Laura Liebhart, of Denver; *Assistant Recording Secretary*, Dr. H. H. Bucknum, of Denver; *Treasurer*, W. F. McClelland, of Denver. The meeting was the largest and best the society has ever held. Over a hundred-and-fifty members were present. Sixty papers were presented, and addresses were delivered by Professors Ridlon and Vaughan. A number of social features were introduced, and the meeting was voted a success. Sixty-two new members were added to the membership list.

Meetings of State, National, and International Medical Societies:

	Meets.	Next meeting.
American Dermatological Association.	Sept. 17, 1895	Montreal, Can.
American Electro-Therapeutic Association.	Sept. 3, 1895	Toronto, Can.

Medical Director Albert C. Gorgas, U.S.N., died June 29th, at Germantown, Philadelphia, at the age of sixty years. He entered the navy as an Assistant Surgeon in 1856. From 1889 to 1893 he was in charge of the Naval Hospital at Philadelphia, and after this was on duty at the Naval Museum of Hygiene at Washington.

The Medical and Surgical Reporter has removed from Philadelphia to New York.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVII. SATURDAY, JULY 13, 1895. NO. 2.

ORIGINAL ARTICLES.

THE ETIOLOGY OF DIPHTHERIA.[1]

BY FREDERICK G. NOVY, SC.D., M.D.,
OF ANN ARBOR, MICHIGAN.

OF the infectious diseases there is scarcely one that has passed through as interesting and as remarkable a history as diphtheria. Numerous investigators attempted, at quite an early date, to throw light upon the cause of this dreadful disease. Their efforts, however, were largely unsuccessful, owing to the extreme difficulties presenting themselves at that early period in the study of bacterial affections. In the normal individual the mouth harbors a large number of micro-organisms, and in diseases of the mouth or throat the number and kind of micro-organisms are still further increased. No wonder, then, that this abundant and luxuriant flora of the mouth served to divert and nonplus the early pioneers in this important study.

One thing, however, was certain, namely, that the cause of diphtheria was a microbe—a living organism. It is only too well known that diphtheria is a communicable disease, that it is transmissible from one individual to another. This fact can be explained in but one way, and that is that a living organism is transmitted from one person to another. The attribute of life is essential to the cause of an infectious disease, and diphtheria certainly occupies a front rank in this class.

Our present knowledge regarding the microbic cause of diphtheria may be said to begin in 1883, when Klebs found, by microscopic examination of a number of cases of diphtheria, the bacillus that today is known throughout the world as the cause of diphtheria. During the following year Loeffler succeeded in isolating the bacillus in absolutely pure culture. He was therefore able to describe minutely its morphologic, tinctorial, cultural, and biologic properties, and by so doing furnished a firm, permanent, reliable foundation on which subsequent workers could build with that confidence which has brought about one of the greatest achievements in medicine.

Loeffler confirmed the observations of Klebs regarding the presence of this bacillus in the false membranes of this disease. In twenty-seven diphtheric membranes examined he found the bacillus present in about one-half. On the other hand, in some of the sections examined the bacillus could not be found—a failure due undoubtedly, as he himself points out in 1890, to the fact that some of the early cases studied were not typical cases of diphtheria. Between 1884 and 1890 he examined twenty-one fresh cases of diphtheria, and in every one of these the characteristic bacillus was demonstrated. Inoculations with pure cultures of this bacillus into the trachea of rabbits, guinea-pigs, chickens, and doves produced a croupous-like condition, due to the formation of false membranes. Similar results were obtained by vaginal inoculations in guinea-pigs, and also by applications to the conjunctiva and pharynx. When injected subcutaneously into guinea-pigs a hemorrhagic edema with grayish-white exudate formed.

The fact that the bacilli were always found in guinea-pigs at the point of inoculation, and not within the organs, led Loeffler to conclude that the micro-organisms produced a powerful poison which was absorbed and carried throughout the body. This view was subsequently established by Loeffler's own researches in 1887 and 1888 on the poisonous products of the bacillus, and, above all, by the classic researches of Roux and Yersin in 1888 and of Brieger and Fraenkel in 1890.

Notwithstanding the frequent presence of this bacillus in the disease, and the diphtheria-like results obtained by inoculating animals with pure cultures of the bacillus, Loeffler, with characteristic modesty and reserve, with the true spirit of a scientific investigator, refrained from designating it as the cause of diphtheria. This hesitation was due to several reasons. In the first place, he had found the same bacillus, identical morphologically and physiologically, in the mouth of a healthy child. Again, the typical diphtheric paralyses observed in man were not reproduced in animals; also, when applied to the uninjured mucous membranes of animals, the cultures had no effect. Furthermore, as already stated, the bacillus was not always found in the sections of membranes examined; and, lastly, the bacilli showed a different arrangement in the false membranes from animals compared with those from man. In view of these facts, Loeffler came to the conclusion that, while the bacillus was probably the cause of diphtheria, more investigation would be necessary to prove this relationship definitely.

The doubt expressed by Loeffler as to the relation

[1] Read before the Michigan State Medical Society, June 5, 1895

of the bacillus to diphtheria unquestionably contributed to discourage other investigators, for during the next three years practically no further studies were made. In his second paper, in 1887, Loeffler pointed out the constant presence of the germ in ten cases, and at the same time discovered the pseudo-diphtheria-bacillus, which differed from the bacillus first studied, in addition to slight morphologic and cultural differences, in the absence of any pathogenic power with respect to guinea-pigs.

In the following year Hofmann, whose untimely and tragic death will ever remain in the memory of bacteriologists, studied the occurrence of the Klebs-Loeffler bacillus in diphtheria. He succeeded in finding the bacillus in six out of eight cases, but he failed to establish any specific relation between the bacillus and the disease, for much the same reasons that led Loeffler to question the correctness of his own interpretations. Thus Hofmann met with the non-pathogenic, pseudo-diphtheria-bacillus in diphtheric membranes and also in twenty-six out of forty-five diseased but not diphtheric mucous membranes. He likewise demonstrated a marked variation in the virulence of the Loeffler bacillus obtained from different cases, and from old cultures. Furthermore, the virulent bacillus was found in a case of measles, and in one individual out of eleven in whom no throat-complication existed.

In December, 1888, Roux and Yersin published their first memoir on diphtheria, in which they were able to take the definite stand that the Klebs-Loeffler bacillus was the specific cause of diphtheria. They considered themselves justified in taking this position because: (1) they found the Loeffler bacillus present in each one of the fifteen cases of diphtheria examined; (2) by means of pure cultures of the bacillus they reproduced false membranes in animals, just as Loeffler had done; (3) they succeeded with pure cultures in producing paralyses in animals similar to the post-diphtheric paralyses in man; (4) they demonstrated that the bacillus gives rise to poisonous products which, when injected into animals, produced either death or paralyses, according to the dose. This publication of Roux and Yersin attracted widespread attention, and led numerous workers to take up the subject of the etiology of diphtheria. The result of these investigations was the confirmation of Roux and Yersin's conclusions, and, with this achievement once accomplished, it became possible for Behring to enter definitely upon that research which has given, and will give, invaluable benefits to mankind.

Let us consider now, in a somewhat general way, the evidence that has been brought forward during the past ten years regarding the etiology of diphtheria. In the first place, in order that a micro-organism shall be considered as the cause of a disease, the requirement is exacted that it shall be found in every case of that disease. This so-called first rule of Koch, framed at a very early period in the history of the etiology of infectious diseases, assumes some things that, in the light of our present knowledge of the *rôle* of micro-organisms in infection, cannot be disregarded. Thus, that which for clinical or anatomic reasons is described as a definite disease may in reality be far from being an entirety. A rational or natural classification in general biologic science is based upon natural, intimate relationships, and not upon mere appearance or form. The division of diseases by the clinician, based on mere clinical observations, or by the pathologic anatomist, based on anatomic relations, are largely classifications of convenience, and in no wise bring out the relation that is closest and most intimate to the disease—that of the cause. It does not require much reasoning to show that what is clinically or anatomically designated as a disease may have only one cause or may have several distinct causes. In the latter case, what was called a disease becomes, through the study of its etiology, a group of diseases. The old typhoid fever has passed through such a history, and we may say in advance that diphtheria has recently experienced a similar development.

We may now ask ourselves, Is the Loeffler bacillus present in every case of diphtheria? Is the first rule of Koch demonstrated? From the earliest investigations of Klebs in 1883, and of Loeffler in 1884, until the present day, it is evident that the Loeffler bacillus is present in a very large proportion of the cases of clinical diphtheria. In the following table an effort is made to compile all available reports of bacteriologic examinations, from outside the United States, of diphtheria, made in ten cases or more, showing the number of cases examined and the number of times the Loeffler bacillus has been found:

	No. of cases examined.	No. of times Loeffler bacillus found.		No. of cases examined.	No. of times Loeffler bacillus found.
Sörensen, 1886	10	7	Baginsky, 1892	154	118
Roux & Yersin, 1888	15	15	Hoppe-Seyler, 1892	37	23

Sakharoff, 1892	19	13			
Tangl, 1892	18	18			
				2846	2344
			Percentage,	.....	82.4

From this table it will be seen that in 2846 cases examined by European workers the Loeffler bacillus was met with 2344 times, or 82.4 per cent. The result is somewhat higher than that obtained by American investigators, who, it will be observed, largely through the efficient support of the Board of Health of the City of New York, examined nearly twice as many cases as given in the preceding table.

	No. of cases examined.	No. of times Loeffler bacillus found.
Park, 1892	140	54
Park, 1893	104	73
Park and Beebe, 1894	4795	3255
Morse, 1894	301	217
	5340	3599
Percentage	.....	67.5

If we now combine the results obtained by American and European workers, we shall have 8186 cases, in which the Loeffler bacillus was found 5943 times, or in 72.6 per cent. of the cases.

These two tables contain the results obtained by a large number of investigators, in different laboratories and in different countries, employing at times methods more or less different. In many instances, the cases examined are described as suspicious or very suspicious. The degree of suspicion, as Welch has pointed out, is a relative one, depending on the physician, for when one physician considers a case to be highly suspicious, another may regard it as very doubtful. Accurate, positive clinical diagnosis of diphtheria in many of the foregoing cases is lacking, and the low percentage that these statistics furnish may in part at least be explained by this dilution with suspicious cases. For purposes of diagnosis, of course, the examination of suspicious cases is extremely valuable, but in statistics intended to show the frequency of the Loeffler bacillus in diphtheria they can have but one effect, that of lowering the percentage. This is true in the two tables already given and in the third table, which serves as an excellent comparison with the work of the American bacteriologists, giving the results obtained by the French investigators of the Pasteur Institute of Paris.

These results, it will be observed, are obtained by men working in the same laboratory, employing the same methods of research, and studying cases in one and the same hospital. These figures are already included in the first table. It will be seen from this table that the Loeffler bacillus was found in 73 per cent., which coincides closely with the percentage-frequency in all cases examined. Bearing in mind that these French bacteriologists are all skilled workers, it will be evident that this percentage is low because of errors in diagnosis by the internes of the hospital.

	No. of cases examined.	No. of times Loeffler bacillus found.
Roux and Yersin, 1888	15	15
Roux and Yersin, 1890	80	61
Martin, 1892	200	137
Sakharoff, 1892	19	13
Chaillou and Martin, 1894	198	155
Roux, Chaillou, and Martin, 1894	448	320
	960	701
Percentage	.....	73

The available statistics then show that 73 per cent. of all clinical and suspicious cases of diphtheria contain the Loeffler bacillus. That this percentage will be higher when greater care is taken in diagnosis, excluding suspicious or doubtful cases, is evident. Furthermore, there are other conditions that bear upon the detection of a given micro-organism in disease, and all of these factors tend to lower the percentage. Thus, in the first place, the accuracy and skill of the individual in detecting the Loeffler bacillus are to be considered. The more experience one has in this kind of work, the more easily and frequently will the bacillus be found. Again, much will depend on the method of staining and on the method of cultivation. Certain stains are preferable to others, and the same is true of the medium on which the germ grows. Again, failure of detection may result from conditions over which the bacteriologist has no control. Thus, the material which is removed from the throat may not be from that portion where the Loeffler bacillus is present. Mere touching or scraping of the surface of the membrane does not necessarily carry with it the bacillus, which may, however, be present in the membrane. Again, the Loeffler bacillus may be present, but outgrown by the large number of foreign germs that may be present. In such cases the detection of the germ becomes a mere accident. Further, the bacillus may be inhibited or even prevented in its growth on culture-media by a previous application of antiseptics to the throat. That such cases may and do occur has been shown recently by Plaut.

There is reason, therefore, to believe that the percentage of cases of diphtheria in which the Loeffler bacillus exists is greater than that given in the preceding statistics. With proper care in diagnosis and in the removal of portions of membrane from the throat, supplemented by skilled investigators using reliable, well-tried methods, the percentage of cases in which the Loeffler bacillus is found may rise to a marked extent, as seen from the following table.

	No. of cases examined.	No. of times Loeffler bacillus found.
Phillips (Baginsky)	333	332
Bernheim	12	11
Hilbert	11	11
Katz	128	128
Kossel	117	117
Loeffler and Strübing	100	75
Ritter	225	225
Bergmann	46	46
Fraenkel	about 1...	in all but few
	972	945
Percentage		97.2

These figures are already included in the first table. They were all obtained during the past year (1894) by German workers. Plaut's results are omitted because most of his cases were diagnosticated as "suspicious" or "very suspicious."

In connection with the presence of the Loeffler bacillus in diphtheria it should be emphasized, contrary to Hansemann, that there are cases in which the bacillus is present in perfectly pure culture, unaccompanied by any other germ. This is especially true if the examination be made at an early stage, as has been demonstrated by Martin, by Chaillou and Martin, by Fraenkel, and by others. Subsequently, as the disease progresses, other bacteria, especially cocci, make their appearance, and may not only outnumber but even suppress the Loeffler bacillus.

These bacteriologic studies with reference to the frequency of the Loeffler bacillus in diphtheria demonstrate clearly that this bacillus is present in more than the 75 percentage of all cases of real clinical diphtheria, as stated by Loeffler and conceded even by Hansemann. There remain, however, still a sufficiently large percentage of clinical diphtherias from which the Loeffler bacillus is unquestionably absent. In these cases, which, in many respects, are undistinguishable clinically from those in which the Loeffler bacillus is present, other micro-organisms are found. These forms of diphtheria may be due to several other micro-organisms, as has been shown by Roux, Chaillou, and Martin in their researches. They cannot be said to be proved to be causes of such diphtherias, but, nevertheless, there is much reason to believe that such is the case.

The French bacteriologists divide anginas into two groups: First, diphtheric anginas, those in which the Loeffler bacillus is present; and, second, non-diphtheric anginas, those in which it is absent and which, as stated, are undoubtedly due to other micro-organisms, above all to cocci. Thus in 112 anginas examined by Martin, 69 were found to be diphtheric and 43 non-diphtheric. The most common organism found in the latter group in 25 cases was a coccus. The next most common organism was the streptococcus, found in 8 cases, and in a few others the staphylococcus albus, aureus, and other cocci predominated.

In a second series by Chaillou and Martin, 99 anginas were examined, and 70 were found to be diphtheric and 29 non-diphtheric. Of the latter, 11 had the small coccus of Brisou, 11 had streptococci, and 4 had staphylococci. In the 448 cases examined last year by Roux, Chaillou, and Martin, 128 were found to be non-diphtheric. The study of croup by these same observers has likewise demonstrated that all croups are not diphtheric. They may likewise be divided into diphtheric and non-diphtheric croups. The latter, as in the case of the anginas, may be due to the Brisou coccus, the streptococcus, the staphylococcus, and other organisms. As seen from the subjoined table, the number of non-diphtheric croups is much less—nearly one-half—than the non-diphtheric anginas:

	No. of cases.	Diphtheric	Non-diphtheric.
Anginas:			
Martin	112	69	43
Chaillou and Martin	99	70	29
	211	139	72
Percentage	....	.....	34.1
Croups:			
Martin	88	68	20
Chaillou and Martin	99	85	14
	187	153	34
Percentage	...	...	18.2

The bacteriologic examinations show clearly, therefore, that diphtheria, as it is commonly understood, may be due to several causes—in other words, that we have a group of diseases that clinically often cannot be distinguished, but that, nevertheless, are etiologically different. It has been proposed to designate those cases in which the Loeffler bacillus is present as true diphtheria, or bacillar diphtheria, or diphtheria, for short; while those cases in which it is not present are spoken of as false diphtheria or pseudo-diphtheria, coccus-diphtheria, or diphtheroid.

Inasmuch as those cases in which the Loeffler bacillus is present are most numerous and most fatal, this form of diphtheria above all requires our attention. What evidence do we possess, then, that the Loeffler bacillus is actually the cause of those cases of diphtheria in which it occurs?

In order to prove this relationship it is necessary to obtain the bacillus in perfectly pure culture, free from all other micro-organisms. This can readily be accomplished, thus satisfying the second rule of Koch. The pure cultures thus obtained, when inoculated into susceptible animals, must now produce the same disease, with all its symptoms and pathologic changes, and in the animal thus artificially infected the germ is to be found distributed the same as in the natural case. This severe requirement is rarely complied with, for the reason that the animals which are used for experimentation, while susceptible to the action of the germ, can scarcely be expected to reproduce all the details of the disease as it exists in man. Thus the bacillus of glanders, which has been shown to be the cause of glanders in the horse, producing in that animal typical glanders, will, if inoculated into a field-mouse, produce death, but without the slightest resemblance to the disease in the horse. In other animals, as the guinea-pig, the bacillus does produce effects strikingly like those of glanders. Other instances might be cited to show that when experimenting with bacteria on animals other than those in which the disease naturally occurs, variations are met with and must be expected. What, then, is

the effect of the Loeffler bacillus when inoculated into susceptible animals?

Fortunately, the results obtained by such inoculations are so striking and bear so great a resemblance to the natural disease in man as to leave no doubt in the minds of those who are at all familiar with the work that has been done in this direction. The production of experimental diphtheria in animals by Loeffler, and above all by Roux and Yersin, is in itself sufficient to show that the Loeffler bacillus is the cause of diphtheria. Guinea-pigs, pigeons, and rabbits are most susceptible to the Loeffler bacillus. Subcutaneous injections of a virulent culture into these animals almost invariably produce death in from twenty-four to forty-eight hours. A more or less extended gelatinous edema forms at the point of inoculation; a grayish pseudomembrane forms and the glands are enlarged. Serous effusions in the pleura are common in the guinea-pig, but very rare in rabbits. On the other hand, the liver in guinea-pigs is apparently unaffected, whereas in the rabbit fatty degeneration takes place. The inoculations on the mucous surfaces are especially characteristic. In order to succeed, the mucous membrane must first be slightly injured; otherwise infection does not result. Inoculations in the pharynx, trachea, conjunctiva, and vulva of animals are followed by the formation of false membranes, general intoxication, and death. In tracheal inoculations the false membranes may spread, as Fraenkel points out, covering the entire walls of the air-passages even as far as the large bronchi. The tissues are edematous and the glands swollen. A more striking resemblance to the natural disease can hardly be expected in animals that are not naturally susceptible to the disease.

The post-diphtheric paralyses observed in man have also been reproduced in animals by Roux and Yersin, Brieger and Fraenkel, and others. These paralyses are especially well marked in pigeons, rabbits, and dogs that have been inoculated with a quantity of the germ insufficient to kill in a short time. In from six days to two or three weeks from the inoculation typical paralyses develop and the animal either recovers or eventually dies. The production of false membranes on mucous surfaces and subsequent paralyses in animals complete the resemblance to the natural disease to such an extent as to establish the specific relation of the Loeffler bacillus to diphtheria.

Not only can pure cultures of the bacillus cause the paralyses in animals, but the chemic products of the bacillus can accomplish the same result. The researches of Roux and Yersin on the poison produced by the Loeffler bacillus mark a new era in the study of diphtheria. The filtered, germ-free cultures of the Loeffler bacillus, when injected into rabbits in doses not sufficient to kill in a short time, produce typical paralyses. That similar poisons are elaborated in the body of diphtheria-patients has been demonstrated by these investigators and by others. Thus, the spleen and urine of a child dead of diphtheria were shown to contain the same or similar poisons that, when injected into a rabbit, were followed by prolonged paralysis and death.

The effect of pure cultures of the Loeffler bacillus and of its chemic products on animals may be said to establish its relation to diphtheria. There are, however, two other facts that still further emphasize this relation. In the first place, the high mortality of those cases of diphtheria in which the Loeffler bacillus is present is in striking contrast with the mortality of those cases in which it is absent. This is no accident, much less a myth, as Hansemann would believe.

In the 80 cases studied by Roux and Yersin in 1890, the Loeffler bacillus was present in 61 cases and absent from 19. All of these 19 recovered, whereas of the 61 cases in which the bacillus was present 30 died. Again, of the 200 cases examined by Martin in 1892, the Loeffler bacillus was found in 137 cases and was absent from 63 cases. Of 55 non-diphtheric anginas and croup 7 died; 4 of these, however, became infected with the Loeffler bacillus in the hospital, subsequent to tracheotomy, and 1 died of broncho-pneumonia. Of 137 diphtheric anginas and croups 72 died. The study of the 198 cases presented by Chaillou and Martin in 1894 develops the same remarkable difference in the mortality of the two groups. Thus, in the 198 cases of angina and croup mentioned, the Loeffler bacillus was found 155 times and was absent from 43 cases. Of the 43 non-diphtheric cases 4 died, 3 of these as a result of subsequent infection in the hospital with the Loeffler bacillus. Of the 155 cases in which the Loeffler bacillus was present 83 died. Again, of the 448 cases reported on by Roux and his coworkers last year, treated with serum, 109 died; 320 of these cases had the Loeffler bacillus, and gave a mortality of 98; 128 did not have the Loeffler bacillus, and gave a mortality of 11.

These figures are brought together in the following table, and furnish an interesting subject for study:

	No. of cases with Loeffler bacillus.	Deaths.	Per cent.	No. of cases without Loeffler bacillus.	Deaths.	Per cent.
Roux and Yersin	61	32	49.2	19	0	0
Martin	137	72	52.0	55	7	12.7
Chaillou and Martin	155	83	53.5	43	4	9.3
Average	353	185	52.4	117	11	9.4
Antitoxic serum: Roux, Chaillou, and Martin	500	58	26.0	128	11	8.6

The bacteriologic examination of clinical diphtheria, therefore, shows clearly that the mortality in those cases in which the Loeffler bacillus is present is about 50 per cent. On the other hand, those forms that are clinically undistinguishable from the preceding, but do not contain the Loeffler bacillus, possess a mortality of 10 per cent., which, however, includes those that died of subsequent infection with the Loeffler bacillus. Deducting these, assuming that all would recover, the mortality would sink to less than 4 per cent. Certainly no more remarkable evidence of the etiologic relation of the Loeffler bacillus to diphtheria can be presented than that shown from the study of the relative mortalities.

As a final proof of the relation of the Loeffler bacillus to diphtheria, we will mention in a general way the results obtained from the use of the antitoxic serum. First of all, it is desirable to emphasize the experimental fact that the serum of animals rendered artificially immune to the diphtheria-bacillus or its products will protect absolutely animals against many times the fatal dose of the diphtheria bacillus or of its poison. This fact is as well established by direct experimentation on animals as the chemic fact that sodium hydroxid and hydrochloric acid neutralize each other. Secondly, it will be remembered that in diphtherias in which the Loeffler bacillus is present, poisons the same as those formed in pure cultures are produced and can be found in the organs, as has been done by Roux and Yersin and others. The antitoxic serum that protects animals against infection with the Loeffler bacillus must likewise protect the person afflicted with diphtheria due to the Loeffler bacillus. That it actually does protect is abundantly demonstrated by treatment of diphtheria during the past year.

To emphasize the statement already made, it will be sufficient to present one or two instances. Of the 300 cases treated with the antitoxic serum and reported on by Roux, at Budapest, last September, only 78 died, giving a mortality of 26 per cent. These results were obtained in the same hospital in which Chaillou and Martin established the fact that in diphtheria in which the Loeffler bacillus is present the mortality is above 50 per cent.

Furthermore, showing the specific action of the antitoxic serum on the Loeffler bacillus and its products, it will be seen, from results already cited, that in 128 non-diphtheric cases treated the mortality was 8.6 per cent. against 9.4 per cent. in non-treated cases. The serum is, therefore, without any effect in cases in which the Loefiler bacillus is not present, and in those cases in which it was present the mortality was reduced by one-half, that is, 25 per cent. were saved. Since then the mortality-record has been lowered considerably. Thus, in 128 cases of diphtheria containing the Loeffler bacillus, treated by Katz, only 17 died, giving a mortality of 13.2 per cent.; 117 cases treated by Kossel gave 13 deaths, a mortality of 11.1 per cent.

Because the protection against the Loeffler bacillus is absolute in animals, it must not be expected that similar results will be obtained in man. A certain mortality will necessarily exist, owing to conditions over which the physician can have no control. In experiments on animals, three factors are involved : the animal body, the Loeffler bacillus or its poison, and the antitoxic serum. It is well known from experiments that an animal cannot be saved when the duration of the disease or of the intoxication has been too long. Irreparable injury has already been done. The same results must, therefore, be expected in the human subject when the disease has progressed beyond a certain point.

Furthermore, in the human subject, in addition to the three factors mentioned, another one is to be considered, and that is the association of the Loeffler bacillus with other micro-organisms. It is to-day a well established fact in bacteriology that a given pathogenic germ may be favored or retarded in its action by the presence of other organisms. In diphtheria, both of these conditions are not infrequently met. Roux and Yersin have shown that the virulence of the Loeffler bacillus, with respect to animals, is increased by associating it with the streptococcus of erysipelas. The statistics furnished by Chaillou and Martin are especially valuable in this regard. In their researches, as already stated, the cases of clinical diphtheria were divided, on the strength of the bacteriologic examination, into diphtheric and non-diphtheric. The diphtheric anginas and croups were subdivided into (1) pure diphtheric forms, in which the Loeffler bacillus was present in a pure or almost pure condition; (2) diphtheric forms with microbic associations. The latter associations may vary. At one time there is present a small diplococcus, the coccus of Brisou; at another time a streptococcus; at another time a staphylococcus. In a few words, the same germs that are found in non-diphtheric forms may be associated with the Loeffler bacillus in real diphtherias.

The following table, compiled from the results obtained by Martin in 1892, and by Chaillou and Martin in 1894, demonstrates clearly the effect of microbic associations. All these cases contained the Loeffler bacillus. Those designated as "pure diphtheric" contained the Loeffler bacillus in almost pure culture, the number of foreign germs being very small, if at all present. In those cases designated as coccus-angina or croup, the predominating foreign germ, beside the Loeffler bacillus, was a small diplococcus. It will be observed that the percentage-mortality in this group is much less than in the group of pure diphtheric affections. In other words, the presence of a large number of cocci of this

kind tends to counteract the effect of the Loeffler bacillus. In the third group are included those cases in which, in addition to the Loeffler bacillus, streptococci or staphylococci predominate. Here it will be noticed that the percentage-mortality is much greater than in the pure diphtheric forms. The streptococci and staphylococci, therefore, either increase the pathogenic powers of the Loeffler bacillus directly, or by their own products give rise to additional intoxication, and, therefore, increased mortality:

	No. of cases.	No. of deaths	Per ct.	Per ct. both anginas and croups.
Anginas:				
Pure diphtheric	96	38	40	
Diphtheric with coccus	14	1	7	
Diphtheric with streptococci or staphylococci	29	26	90	
Croups:				
Pure diphtheric	67	44	66	50.3
Diphtheric with coccus	19	5	26	18.2
Diphtheric with streptococci or staphylococci	25	19	76	83.3

There are a number of other interesting points regarding the Loeffler bacillus, such as the presence of this germ in the throats of healthy children; its occurrence in fibrinous rhinitis; in wound-diphtherias; its persistence in the throat after recovery from diphtheria; its relation to the non-virulent pseudo-diphtheria-bacillus, etc. These facts, however, have but little significance, so far as the proof of the relation of the Loeffler bacillus to diphtheria is concerned, and I shall, therefore, avoid their discussion.

Summarizing briefly the leading points brought out in this paper, it will be seen, *first*, that the Loeffler bacillus is present in much more than 73 per cent. of real clinical diphtherias; *second*, that pure cultures introduced into animals reproduce false membranes, paralyses, and other ill-effects observed in diphtheria; *third*, that the chemic products of the bacillus produce paralyses, diarrhea, intoxication, and death, completing the resemblance to the natural disease; *fourth*, that the mortality is vastly greater in those cases in which the Loeffler bacillus is present than in those from which it is absent; *fifth*, that the antitoxic serum, which possesses a specific action toward the Loeffler bacillus and its poison, reduces the mortality in those cases in which the Loeffler bacillus is present and is without effect in those from which it is absent.

It is this overwhelming evidence that fully justifies us in stating that whenever the Loeffler bacillus is found in a disease it is diphtheria. It was with genuine pleasure that Loeffler could make the definite announcement at Budapest last year, ten years after his pioneer work of 1884, that "The cause of diphtheria is the diphtheria-bacillus."

A NOTE ON THE TREATMENT OF CATARRHAL DEAFNESS BY PNEUMO-MASSAGE AND PHONO-MASSAGE.

BY C. JAY SELTZER, M.D.,
OF PHILADELPHIA;
AURIST AND LARYNGOLOGIST TO THE PHILADELPHIA HOSPITAL

DEAFNESS due to catarrhal inflammation comes on so insidiously that the impairment of hearing is not noticed in most cases until the conduction of sound is greatly impaired in one ear, if not in both ears. A desire to secure relief without resort to surgery calls for many efforts to devise some form of mechanism by means of which the delicate membranes and bony arches may be restored to their normal condition of elasticity and mobility. This can be best accomplished by a process of exercise or massage, associated with constitutional and local medication.

The Edison phonograph, the vibrometer, and the vibrophone have all been before the medical profession for some time, with strong claims urged for each of them. These instruments fulfil the indications in part by producing a series of aërial impulses which are conveyed to the ear by means of tubes attached to an artificial drum in the instrument, and terminating in suitable bulbs that closely fit the external meatus. The diaphragm of the artificial drum being put into vibration causes a similar movement of the membrana tympani and associated ossicles in the middle ear, thus breaking up some of the adhesions due to deposits of plastic material and inspissated mucus. This movement generally relaxes, and if sufficiently long continued permanently lessens the tension caused by such adhesions, and at the same time frees the drum of the inspissated mucus which mechanically interferes with sound-conduction. This continued action upon the drum, moreover, tends to stimulate the normal secretion of mucus, and thus slowly softens the inspissated masses, which may be dislodged and expelled into the upper pharynx. At the same time it admits of freer ventilation of the middle ear, and consequent equalization of air-pressure inside and outside of the drum, thereby removing one source of tinnitus.

The vibrophone does not possess sufficient force to produce more than very mild impacts, and is, therefore, much inferior to the vibrometer or the phonograph. The vibrometer has one advantage over other instruments in that the vibrations produced by one or the other of the banjo-strings possess a pitch and tone that are agreeable to the patient and sufficiently mild to admit of long sittings. The best instrument for the purpose, however, is the phonograph, which, with the proper diaphragm attached, possesses the maximum of force with the minimum of sound. Such a diaphragm, with the attachment for the stylus, was devised some four years since, and although very delicate in construction, makes a

sufficiently strong attachment for use on the grooved wax-cylinders ordinarily used on the phonograph.[1]

With this diaphragm, and the cylinders grooved as the operator may desire, very forcible impacts with greatly reduced noise can be produced, and can be easily regulated to suit the conditions in each case. This is accomplished with comfort and safety for the patient owing to the movement of the diaphragm which causes the drum to retract, thereby producing, or tending to produce, a partial vacuum by first drawing out the membrana tympani and relieving the internal ear from pressure, and then alternating the pressure as the diaphragm returns to its original position, thus rapidly and continuously putting in motion the membrana tympani and the ossicles, without increasing the pressure on the oval window, and without possible harm to the internal ear.

The phonograph has an additional advantage in that the confusion sometimes complained of when long-continued applications of massage have been made is nicely relieved by substituting a musical cylinder, which is both entertaining and soothing, especially stringed-instrument records, such as of the banjo. The vocal cylinders can be used to determine the quality of sound-conduction as well as the hearing-value, and the orchestral musical cylinders in determining the pitch and kind of instruments best heard and recognized. We may also note the degree of improvement as shown by the additional words and tones recognized and repeated from time to time. The phonograph is, therefore, decidedly the best and neatest instrument for producing what is called pneumo-massage and phono-massage, with the single exception of certain gentle musical vibrations which can be best obtained from the banjo-strings of the vibrometer.

The cases should first be carefully examined, to determine as nearly as possible the seat of pathologic change, the character of deafness as regards the quality of sound, and the sensitiveness both to pain and sounds caused by the instrument in producing vibrations. The instrument is then started at a low speed, which is increased until discomfort or a tendency to vertigo is felt, at which point the maximum limit is reached. The speed is then reduced to a velocity at which comfort is expressed, and retained at that point for several sittings, but may be gradually increased at subsequent sittings. The sittings should be regulated in length of time by the sensations of the patient, so as to avoid mental and physical discomfort (usually from ten to twenty-five minutes), and end by an agreeable musical cylinder, thus diverting attention to pleasant sensations, and at the same time securing mild auditory exercise.

[1] Messrs. Hawthorne & Sheble, the Edison phonograph agents of Philadelphia, 604 and 606 Chestnut Street, have been preparing these cylinders and diaphragms for this purpose after the original model made by Mr. Leeds.

The results of this method, in conjunction with proper alteratives and tonics, and local treatment consisting of applications of tannic acid and glycerol, or weak silver-solutions to the naso-pharynx, antipyrin, and compound tincture of benzoin to the nose (especially over the lower turbinated bone), followed by camphor and menthol in liquid vaselin, and when stenosis from engorgement exists the galvano-cautery applied, will result in marked improvement in many cases of deafness in which the loss of delicacy in motion of the conducting bony chain is caused by pathologic changes not destructive to the continuity of soft or bony tissue. A thorough trial of this method in a large series of cases covering a period of twelve months has convinced me that an absolute cure or return of normal hearing-power in a large proportion of these cases may not be possible, but a considerable number will show the most marked improvement, while in the remaining cases an arrest of progress may at least be expected. Associated tinnitus is likewise relieved or cured in many cases, but a few will yield in neither deafness nor tinnitus in the period mentioned.

The disadvantages of this method are the length of time required and the number of applications necessary to accomplish the desired result; but, notwithstanding these faults, it promises at present the greatest degree of success with the least amount of injurious effects of any method yet proposed, and is altogether our surest method of relief when used in connection with the proper inflation of the middle ear and the necessary local and constitutional treatment.

ORIGINAL ADDRESS.

ADDRESS IN MENTAL DISORDERS.[1]

By F. X. DERCUM, M.D.,

CLINICAL PROFESSOR OF NERVOUS DISEASES, JEFFERSON MEDICAL COLLEGE; NEUROLOGIST TO PHILADELPHIA HOSPITAL; CONSULTING PHYSICIAN TO THE HOSPITAL FOR THE CHRONIC INSANE AT WERNERSVILLE, PENNA.

For many years the public mind in dealing with the problem of insanity has approached it almost exclusively from a practical and utilitarian point of view. The reasons are obvious. The position that insanity and all that pertains to it has occupied in the past has been most peculiar. For ages the insane had been treated as a class that required not only the isolation of the leper, but also the punitive treatment of the evil-doer. In the lay mind insanity involuntarily excited abhorrence and disgust, and was closely associated with ideas of blame and punishment. Indeed, in this day it is by most people regarded as a disgrace if one of their relatives become insane, and often the fact is as much as possible kept concealed. By some unaccountable action of the human mind this peculiarity attaches to no other class of diseases;

[1] Read before the Medical Society of the State of Pennsylvania, at Chambersburg, May, 1895.

at least not in the same degree. It is not strange in view of these facts that the first attempts at the management of the insane in bulk consisted mainly in their housing, and made no other provision for their welfare. Even in these days, when the insane are placed under the care of physicians, the latter are assigned rather the duties of housekeepers, stewards, and executive officers than those of medical attendants. When we consider the attitude of the public mind that obtains more or less to this day, and when we consider the inherent difficulties of the subject, we can readily understand why the science of insanity, especially its pathology, has remained a veritable Africa to medical men.

We must, however, frankly admit that in the practical care of the insane an enormous advance has been made —an advance that has continued unceasingly ever since the days of Pinel, of Tuke, and of Rush. We, too, often look with eyes of reproach upon the science and forget the great practical good that has been accomplished in other directions. Surely the pathway through the jungle had first to be cleared, a semblance of order had first to be established, a knowledge of clinical forms had first to be acquired, before the explorers of this dark continent could devote their time to purely scientific study. In this struggle, in this gigantic task, the alienist is still engaged.

We cannot be surprised that more has not been accomplished when we reflect that the asylum of to-day is only the refined madhouse of former times, and that in it but few opportunities for scientific research are to be found; and, further, to repeat, that the physicians are burdened with executive duties such as should not come within the province of medical men, and of which medicine as a science can take no cognizance.

For this condition of affairs medical men are not to be held strictly accountable. The insane-hospital is for the most part a public institution, and its organization, the plan upon which it is conducted, the financial system upon which it is based, is a reflection of public opinion. The practical politician fails to see the advantages resulting from purely abstract scientific investigation, and yet it is very probable that an increased knowledge of the pathology of insanity will diminish not only the cost of maintaining the insane, but also the actual number to be maintained.

Another and still more serious obstacle has confronted the student of psychiatry, indeed the greatest obstacle of all, and that is the inherent difficulty of the subject. The alienist has been in the unfortunate position of being able to observe surface-indications only, while of the actual underlying principles he could of necessity have no knowledge, inasmuch as both the structure and the function of the gray cortex, except in their grossest relations, were unknown. As a consequence, metaphysical reasoning and vague speculation for a long time took the place of fact and scientific observation.

At last the difficulty promises to be removed; the dawn of a better day is at hand; the marvellous methods of research of Golgi and of Ramon y Cajal, in the hands of such men as Lloyd Andriezen,[1] are revealing the actual, the detailed structure of the human cortex. The beginning has been made of associating structure with mind-action, and the recognition of the fact that mind-action cannot be separated from ordinary brain-action must henceforth be accepted as an indisputable fact. Doubt, prejudice, preconceived notions of all kinds must yield to scientific truth.

Andriezen has analyzed and separated the various elements of which the gray cortex is composed, and the relations of the structures to each other are such that their function seems evident. The incoming, the afferent, fibers, which bring information to this vast expanse of ganglionic matter, the gray cortex, terminate not in ganglion-cells, but in the uppermost layer, the molecular layer, of the cortex. Here their minute divisions come in contact with the minute branches and delicate tufts of the various cortical cells. Significant is it, too, that the insulating material that encircles this afferent fiber is lost when the fiber enters the cortex, so that there is no interference with the proper diffusion, either by contact or induction, of the current which it conveys to surrounding structures. The current, whatever its mode of motion may be, is transferred from cell-process to cell-body and thence perhaps to afferent fibers, or more frequently to countless numbers of other cells—cells whose business it is to associate, to combine, to separate, and to store up impressions.

The limits of the time at my disposal will not permit me to enter into a more detailed statement of these discoveries, but their significance is redoubled when we learn that Andriezen obtained the most interesting results when he directed his attention to one of the simpler forms of insanity, namely, one in which the cause is definitely known, and in which the symptoms are well established and relatively simple in character: I refer to alcoholic insanity. Andriezen found, first of all, that the neurons showed changes in the cell-bodies and in the nuclei. There were swelling and indistinct staining of the intercellular chromatin-rods. There were also coarseness and increased staining of the nucleus, changes that indicate that in alcoholic insanity the cell-protoplasm and cell-nuclei are the seat of serious nutritive disturbances. Especially, however, did Andriezen note alteration and destruction of the fine naked collaterals and nerve-terminals of the molecular layers of the cortex—the very layer in which afferent impressions are first communicated to the nerve-cells of the cortex. There were also swelling and softening of the very minute protoplasmic granules attached to the special processes in the superficial quarter of the cortex. These changes, "dynamical changes," as Andriezen calls them, doubtless explain the diminished sensitiveness and alertness of the alcoholic to incoming sensory impressions, and similarly a diminution of the spread of the excitation from one area to associated areas. To these changes and to the changes in the cell-body are also to be relegated the amnesia of the alcoholic state. We have here the first instance in the history of insanity in which it has been possible to correlate closely cause, structural change, and symptom. Surely a beginning has been made in this brilliant research that augurs well for the future.

It is to be hoped that these results will everywhere stimulate the foundation of laboratories in hospitals for the insane. To be sure, a few such laboratories already exist, but too often the pathologist meets with but scant support both from the Boards of Trustees and from the

[1] Brain, Winter Number, 1895; also 1894 Journal of Mental Science, p. 673, abstract.

medical officers of the institutions. Everyone should realize that there is no longer an excuse for the ignorance that exists in reference to the changes in the cortex of the insane. The methods of Golgi and of Ramon y Cajal, as Andriezen has shown, are capable of revealing the most astounding secrets, and one of the most urgent demands upon the time of the alienist should be histologic and pathologic research.

The story, however, does not end here. A second field of work is beginning to claim attention—a field more wide, more vast even than that which has been opened up by Andriezen. After all, whilst the detailed study of the sane or insane cortex will enable us to correlate structure with function and change of structure with change of function, it cannot, save in special instances, as in the case of alcohol, where the cause is clear and self-evident—it cannot of itself reveal the underlying or initial causes that effect these changes. Even if it be possible to correlate the symptoms in the case of mania or of melancholia with dynamic changes in the cell and its processes, it cannot be expected that the agent which produces these changes can be brought to light by this method. After all, the changes that we see are but effects, and are in many instances purely terminal results.

The conviction is steadily growing in the medical mind that the actual agents which produce tissue-changes are chemic agents, toxic substances of one kind or another, no matter what their origin—in one instance absorbed or ingested from without, in another the poison elaborated by bacteria, and in another the poison of altered tissue-metabolism, of abnormal and deranged visceral function.

Unfortunately, we can to-day say little that is fixed and definite upon this subject, and yet enough is known to indicate that we have here vast fields of undiscovered truth. That toxic substances are formed in the blood, that toxic substances are excreted by the urine is well known. This is true both of substances formed by normal and abnormal tissue-metabolism. We need here only allude to the writings of Bouchard upon this subject to recall how the retention of well-known products may cause such symptoms as asphyxia, uremia, uricemia, cholemia, glycemia, etc. A number of French observers, among them Bouchard, Lépine, and Guerin, have isolated alkaloidal substances from normal urine, while Selmi and others have isolated basic substances from pathologic urine. Griffiths, for instance, has obtained ptomains from the urine of scarlet fever, diphtheria, pneumonia, whooping-cough, measles, glanders, and epilepsy. None of these substances exists in normal urine. Luff has isolated a ptomain from the urine of typhoid fever. Albu has discovered ptomains in various pathologic urines, whilst Ewald isolated ptomains from the urine in cases of carcinoma of the stomach, of uremia, and of Addison's disease. It is also known that the urine in melancholia has an increased toxicity, while in mania the toxicity of the urine is decreased while that of the blood is increased. Enough, therefore, is known to justify us in discussing the probable relation of these toxic substances to the nervous system.

That the nervous system is markedly influenced by the presence of toxic substances in the blood is, of course, well known. It remains only to outline a classification of these agents. To begin, certain toxic substances are normal constituents of the blood and urine, and only under certain circumstances are present in excess, when they assert their toxic action. Thus Mosso demonstrated the toxicity of the blood of fatigued animals, while Arbelous demonstrated the same fact not only as regards the blood, but also as regards the muscles of fatigued animals. Lepicque and Marette demonstrated in addition that fatigue increased the toxicity of the urine. It is probable that in these facts is to be sought a partial explanation of some of the phenomena of neurasthenia and of those graver forms of nervous exhaustion that eventuate in insanity. In other words, we have an intoxication of the nervous system in such cases from the mere accumulation of tissue-waste; or, to put it in scientific language, the products of excessive tissue-metabolism.

Closely allied to these substances are those that are present in the various diathetic insanities in which toxins are present, some of which may in smaller quantity be normal to the urine, while others are new and foreign. Thus in the insanity of gout we have doubtless to deal with uric acid, a substance normally present in the blood in small proportion, whilst in rheumatism we deal with a substance new and foreign. This is also true of the toxins of diabetic and of carcinomatous insanity. Regarding carcinoma, it may be stated that the toxicity of the urine is always in excess of the normal, proving thus the presence of some poisonous substance.

Next in order come the various toxic insanities due to disordered visceral action. Regarding these we have but little information. Enough is, however, known regarding the diseases of the kidneys and of the liver to indicate that the insanities associated with these affections are in all probability the result of autointoxication, the poisons being generated in consequence of the disordered action of the viscera. It is not at all improbable that disease of other viscera—probably of all of the viscera—is attended with the elaboration of substances that have a toxic action upon the nervous system, *i.e.*, autotoxins.

Next we should consider the introduction of toxic substances from without, and for the present we shall exclude all poisons ingested as such. From much that we know, we have reason to infer that under certain pathologic conditions poisons are formed in the stomach and intestines which act profoundly upon the nervous system. Massetti, who has especially studied this subject, comes to the following conclusions: First, that if there be a change in the process of gastric digestion by which, as a result of abnormal fermentation, noxious substances are produced, these when absorbed may in a predisposed individual cause disturbance of function of the nerve-centers. Secondly, disturbance of the gastric function secondary to disturbance of the nervous centers may in certain cases lead to the absorption of abnormal materials from the gastro-intestinal tube, which may aggravate a pre-existing mental malady and may retard recovery. Thirdly, the stomach, like the rest of the digestive tube, is, among other things, an organ for the elimination of a toxic principle pre-formed and circulating in the blood. Unfortunately, here, as elsewhere, our knowledge is as yet too indefinite to enable us to speak with precision, and yet the occurrence of intoxication from the intestinal contents is of itself not open to question.

We have still to consider briefly the toxic conditions resulting from infection: for example, influenza, typhoid fever, the eruptive fevers, erysipelas, septicemia, etc. Here the action of the toxic agents resolves itself, as Regis points out, into two separate conditions, depending entirely on the period at which the symptoms of intoxication make their appearance. If these appear during the acute febrile state, they assume ordinarily the form of acute delirium; whilst when they occur during the post-febrile period they produce a mental condition in which confusion, stupidity, stupor, and psychic asthenia are the prominent symptoms. It is not improbable that the symptoms occurring both during the acute febrile period and during the post-febrile state are due to the toxins elaborated by the bacteria of the disease, and are in a sense comparable, the first to the stage of acute alcoholic intoxication, the second to the mental impairment and asthenia of the chronic alcoholic period.

It appears that the various intoxications of the nervous system resolve themselves into two great groups—*first*, the autointoxications, properly speaking, which embrace, first, the substances normal to the blood and secretions, but present in excess; secondly, those substances due to the general disturbance of tissue-change met with in diathetic conditions; and, thirdly, the poisons formed by the disturbed action of special viscera.

In the *second* group we have, first, those substances absorbed from the intestinal tract, some of which are produced, as we have seen, by disordered chemic action and morbid fermentation of its contents, and others normally excreted by the intestinal tract, but under abnormal conditions reabsorbed; secondly, we have the poisons that are the direct results or accompaniments of infection.

While we know comparatively little of the detailed chemistry of these poisons, we are justified in stating the following proposition, namely: that the most diverse agents may produce the same or at least similar clinical phenomena. For instance, the toxic action of alcohol resembles very closely the toxic action of the poison of an infection. The delirium of the febrile period of an infection may closely resemble alcoholic delirium. Again, the insanities coming on in the post-febrile or convalescent period, the so-called asthenic forms of insanity, in which weakness, stupor, and depression are the cardinal features, so closely resemble each other as to be practically indistinguishable. Nevertheless they may result from widely differing infections.

The determination of the toxicity of the urine, of the blood, or of other tissues and secretions implies of necessity experiment upon animals. If an alkaloidal substance be isolated from the urine, its toxicity can alone be demonstrated by experiment. The toxicity of the blood can only be proved by its injection into the veins or into the peritoneal cavity of some animal—a mouse or a guinea-pig. It is to be feared that attempts in this country to prosecute such lines of research may meet with opposition. "Public opinion," which too often is synonymous with public ignorance and public prejudice, may for a time prevent the establishment of experimental laboratories in hospitals for the insane. But perhaps at no very distant day, when it becomes clear that the pecuniary outlay demanded of the State for the care of its insane will eventually be diminished by the prosecution of just such researches, the opposition may be withdrawn. As a matter of fact, every asylum, every hospital for the insane should have attached to it not only a laboratory for the study of the microscopic changes in insanity—changes that by the improved methods now at hand, notably those of Golgi and Ramon y Cajal, promise to yield great results, but also for the determination of the various toxic substances, their origin, their chemistry, and their mode of action upon the nervous centers. As we have already stated, the microscope can at best reveal only the wreckage in the path of the storm, whilst the chemistry of the tissues and of the excretions and experiments upon living animals will enable us to determine the actual causes and the actual sequence of the changes.

That consideration of the pathology of insanity from the standpoint here taken has a practical bearing there can, I think, be no doubt. If it be true that certain of the psychoses are due to intoxication through the stomach, certainly one of the first indications is lavage and other local treatment of the stomach. Indeed, to my mind, it seems good therapeutics to practise lavage in the majority of cases of the depressive forms of insanity, for instance in melancholia and in the various stuporous forms of insanity, not because we believe at this day that these insanities are due to the direct absorption of substances formed by abnormal chemic changes in the stomach, but because it is exceedingly probable that toxic substances even normally excreted by the stomach may, in these conditions, be reabsorbed. Again, if it be true that the psychoses are so largely due to the action of toxins, certainly hydrotherapy, so grossly neglected, acquires a value altogether unexpected. Its application should embrace not only the stimulation of the skin by baths and douches, but also the ingestion of large quantities of diuretic waters. Finally, if the psychoses are due to the action of toxic substances, we shall be in a better position to treat these affections when the action of these toxic agents is known—we shall be in a better position to suggest the proper remedial agents.

CLINICAL MEMORANDUM.

COMPOUND FRACTURE OF THE SKULL, WITH SEVERE LACERATION OF THE BRAIN, IN AN INFANT TWO MONTHS OLD, WITH RECOVERY.

BY CLAUDIUS H. MASTIN, M.D., LL.D. UNIV. PENNA., OF MOBILE, ALA.

THE following interesting case of severe injury to the brain of an infant, less than two months of age, is not without interest, but is worthy of record in the archives of surgical literature. It shows the tolerance of very young children to severe wounds, even when such injuries implicate vital organs. Although familiar with the histories of very many severe injuries to the skull and the brain itself, I am not able to find among surgical records a single case in which so young a child has met with so severe an injury and made so rapid a recovery—if indeed there has been recovery after such an injury.

The following notes, carefully and correctly taken at the time of the injury, will suffice to lay the case before the profession.

On Sunday, April 21, 1895, I was hastily summoned in consultation to see an infant boy, a child of Mr. E. H., the Imperial German Consul at this port. The child had been born February 26, 1895, and was consequently on the day of the accident just fifty-four days old—less than two months. The parents having gone to attend services at church, the nurse, with whom the child had been left, placed it in its little carriage and rolled it upon the front gallery, which is elevated from the ground eight feet, and reached by a flight of rather steep steps, eleven in number. She carelessly left the infant in charge of two little children upon the gallery and went to the rear of the house for some purpose; whilst she was absent, it is supposed the little ones, in play, pushed the carriage toward the landing of the steps, over which it toppled and fell to the bottom and out upon the walk. The child was thrown out at the time the carriage upset, and, in falling, the little steel rod which supports the sunshade struck the frontal bone just above the orbital ridge over the right eye, penetrating the skull and entering the brain to the distance of about three-quarters of an inch. (I *estimated* this depth from the stain of blood and brain remaining upon the rod.) Entering the skull with much force, it appeared to have torn itself outwardly as the child, which evidently had been impaled upon the rod, fell away from the carriage. The wound extended upward and outward on the right side of the frontal bone, from just above the orbital ridge, near to the sagittal suture, a distance of very near, if not entirely, two inches. The rod measured three-eighths of an inch in diameter, and at the point was rough and jagged, just such an instrument as would be calculated to inflict such an injury. There was considerable loss of blood, and at least a dessertspoonful of brain-substance was scattered upon the inside of the sunshade, upon which the child had fallen; besides, an equal amount had been smeared upon the face and some considerable quantity oozed from the wound. The wound was a horrid, lacerated gash, and from it was trickling a flow of dark-colored venous blood, to all appearances coming from the longitudinal sinus. There was no depression of the skull, but rather an eversion of the torn integuments, with a bulging outward of the edges of the fracture, as if they had been forcibly turned out by the rod of steel after penetrating the skull and then ripping up.

The shock was profound, and the child was almost insensible, deathly pale, and pulseless. To all appearances the case was hopeless and surgical efforts were seemingly of little avail—in fact, the child was apparently in *articulo mortis*. Unwilling to abandon the case to a certain death, I concluded to wipe away the extruding brain and close the rent in the forehead, more with the intent of making it a less repulsive corpse than with any hope of effecting a cure! To this end I closed the wound with interrupted silk sutures carried through the scalp and including the pericranium, down upon the skull itself. I was not able, except by pulling aside the edges of the skull, to catch up the dura, else I should have also closed that membrane before closing the integuments. At the point of entrance of the rod, where the integuments were perforated, I left it open for drainage, if perchance the wound should unite. The skull was so soft, very little firmer than a dense sheet of cartilage, that it was an easy matter to bring the edges in close apposition and retain them there by a compress of iodoform-gauze, with a bandage carefully adjusted. As stated, the shock was so profound that the child did not cry or give evidence of the least pain during the introduction of the sutures or in the adjusting of the dressing, being as quiet as if under the influence of an anesthetic. This was about one o'clock in the afternoon, and I had little thought that the child would live through the night. When I again called late in the evening I was astonished to find that reaction was almost complete, with an absence of fever, and that the child had rested quietly and nursed from its mother as it had usually done.

During the night the child suffered a good deal from colic and the temperature had run up to 102°. The infant was restless and irritable. I ordered quiet, and phenacetin, gr. ss, every two-and a-half or three hours until the temperature came down.

On April 23d the temperature had fallen during the night to 99°, the babe had rested quietly, its functions were normal, the bandages were saturated with cerebro-spinal fluid. I readjusted the bandages and found that the flow of fluid was rather profuse, as it ran out and trickled down the child's face. I instructed the mother to absorb it as well as she could, but to avoid any pressure upon the wound.

On April 24th the morning temperature was 98.4°. There was no appreciable change in condition of wound or child. The noon temperature was 99° and at 3 o'clock P.M. it had increased to 100°, but at 7 P.M. had fallen under the administration of phenacetin to 98.4°.

In the morning of April 25th the child was evidently more comfortable, and with the exception of a slight attack of colic during the night had got along very well. At noon the temperature was 99°, and at 6 P.M. it had risen two-fifths of a degree. The wound appeared healed, save at the drainage-point, from which a continued flow of cerebro spinal fluid issued. The child's functions were normal, and it appeared as well as if no accident had happened to it.

On April 26th the child was evidently doing well, and nursed regularly and slept quietly; the temperature remained at 98.4°. The wound appeared soundly healed, save at a small point in the lower angle, from which there continued a rather profuse flow of cerebro-spinal fluid. I concluded to try to arrest this by pressure over the spot, and, having dusted it thickly with boric acid and put on a little compress of gauze, I confined it by a narrow strip of rubber plaster and a bandage. This proved of no avail, for the fluid continued to flow and saturate the dressings, and, as the bandage and plaster seemed to give the little patient discomfort, I concluded to remove all dressing, save a simple fold of gauze to absorb the fluid, and to leave the treatment to the unaided efforts of Nature. The sutures had been removed on the sixth day, and as the wound was entirely closed, save at the minute opening from which the fluid issued, there were no indications to be fulfilled other than quiet, good nursing, and waiting for developments. The next three days, the 27th, the 28th, and the 29th, were passed without any change, with the exception of the night of the 29th, at which time the fluid ceased to flow, and the little opening on the morning of the 30th was closed as tightly as the entire line of wound.

I visited the child again on May 1st and 2d, and finding it perfectly well, with only a narrow line marking

the place where the rent had opened the skull, I concluded to discharge the case from my list.

A few days ago I called to see the little patient and met the nurse with it in the yard. The mother informed me that it had never had a single bad symptom, that all its functions were normal, that it nursed and slept as all her children had done. When questioned as to whether the child was as bright as children usually are at his age, now going into its fourth month, she replied: "Doctor, I think my little boy is the brightest child I have had; he laughs, and plays, and cooes, and is the dearest little fellow in the world."

Such is the outline of this case, which I record as interesting on account of the gravity of the injury, and being followed by such speedy and satisfactory an issue. I might mention the profuse discharge of fluid as exceeding my expectation, although it was not possible to measure the quantity lost, as it was absorbed by the dressings as it issued from the wound; judging from the saturated condition of the gauze, bandages, and little cap which was put on to keep the dressing in place, I feel safe in *estimating* it to have been not less than six or eight fluidounces.

BACTERIOLOGIC NOTE.

A CULTURE-MEDIUM FOR BACTERIA.

BY A. M. BLEILE, M.D.,
PROFESSOR OF PHYSIOLOGY IN THE OHIO STATE UNIVERSITY, COLUMBUS, O.

TO the already long list of culture-media I wish to add the formula of another. White of egg is thoroughly shaken with ten volumes of water, and for every hundred c.cm. of this mixture one c.cm. of hydrochloric acid is added, with a few grains of pepsin, and the whole is kept in the incubator at 40° C. for four hours. The mixture is then neutralized with a solution of equal parts of sodium hydroxid and potassium hydroxid, boiled, and from 10 to 12 per cent. of gelatin or 1½ per cent. of agar added, again boiled and neutralized if necessary, and then filtered.

This medium has been in use in our laboratory for more than a year and has given general satisfaction. It presents several points of advantage over the ordinary media. In the first place, in the summer-time it is difficult to keep the meat-infusion the prescribed time without ice. The egg-medium has the advantage of a greater initial freedom from spores and bacteria; it does away with the use of the somewhat expensive peptone; it requires less weighing and only one filtering; it is fully as rich in nitrogenous matter as the meat-infusion; and it is richer in salts.

NEW DEVICE.

A NEW PLEXIMETER.

BY BOARDMAN REED, M.D.,
OF ATLANTIC CITY, N. J.

IN determining the position, size, and exact boundaries of the accessible abdominal organs, indirect percussion offers distinct advantages over direct percussion. It enables the physician to detect more delicate shades in the percussion-note, such as those between the resonance over the stomach and that over the empty colon, and in determining the boundaries between the colon and the small intestine.

For the new specialty of diseases of the digestive organs, which is now assuming such great importance in the medical world, a good percussor and pleximeter are therefore indispensable. The percussors found in the instrument-stores are generally satisfactory, but not so the pleximeters. All that I have seen hitherto are inconvenient to use, and very awkward to carry in the pocket. The following cut represents a pleximeter I have devised to overcome these defects:

It is made of rubber of medium hardness, so as to be moderately elastic and yet rigid enough to permit of being pressed firmly against the part percussed. The ends are of unequal size, the smaller end usually serving as the handle, but in percussing between the ribs of children, above the clavicle, or in any place where very delicate percussion is necessary, the larger end may be used as the handle, while the smaller serves as the pleximeter.

MEDICAL PROGRESS.

Tonic Blepharospasm Simulating Ptosis.—PERSHING (*American Medico-Surgical Bulletin*, June 1, 1895, p. 662) has reported the case of a lawyer, fifty-four years old, who complained of inability to keep the eyes open, developing in the sequence of excitement and anxiety, in conjunction with excessive smoking and great physical exercise. At first an extra effort was sufficient to raise the lids, but soon the forehead had to be wrinkled and the head thrown back, and sometimes the lids had to be held open with the fingers. For a time the difficulty occurred only in using the eyes in near work, or when they were irritated by the wind. To the patient it seemed that the lids were forcibly held together, and he discovered that pressure on a certain point on each cheek was nearly as efficient in keeping them open as actually holding them apart. Some astigmatism and hyperopia existed, but the muscular balance was perfect. The drainage of tears through the lacrymal duct was imperfect, and their accumulation provoked the spasm. The instillation of a drop of distilled water into either eye also caused contraction. Under the anesthetic influence of cocain the difficulty of keeping the eyes open disappeared. No evidence of organic disease could be detected, and the conclusion was reached that the condition was one of tonic blepharospasm of the orbicularis.

Gonorrhea of the Rectum with Uro-genital Blenorrhea in an Infant.—LEWI (*Archives of Pediatrics*, vol. xii, No. 6, p. 437) has reported the case of an infant, six years old, who, after treatment in a public institution for right-sided empyema, presented a discharge from the vulva and the anus. Just within the anal ring were small erosions, evidently ulcers in the rectal wall. On introduction of a speculum, the mucus membrane for several centimeters above the anal opening was found swollen, angry, spongy, and bleeding easily. Thickened pus, greenish in hue, came from the parts above, indicating

involvement of the rectum higher up. There was a history of rectal tenesmus, with four or five passages daily. Not only were these movements attended with a purulent discharge, but the pus seemed to flow from the rectum in the intervals. The urethral opening was swollen, angry-looking, and discharged pus. The parts about the vulva were much inflamed, and thick greenish pus flowed from the vagina. Bacterioscopic examination of pus from both vagina and rectum disclosed the presence of gonococci. The infection is ascribed to carelessness on the part of a nurse in ordinary ablution, or in the use of an unclean syringe.

Fatal Cerebellar Hemorrhage in a Young Woman, with Glycosuria.—OLIVER (*Lancet*, No. 3742, p. 1237) has reported the case of a woman, nineteen years old, who, while apparently in good health, suddenly lost consciousness. The pupils were contracted and equal, and did not react to light, and there was no paralysis. The pulse was 22 and the respirations 10 per minute. No cardiac murmurs were detected, and there was no peculiar odor of the breath, and no evidence of poisoning. The urine was withdrawn by catheter and contained no albumin, but a large quantity of sugar. Despite active treatment death ensued thirteen hours after the first symptoms. Upon post-mortem examination the only lesion found was a blood-clot in the middle lobe of the cerebellum. The superior surface and the posterior surface adjoining the inferior surface of the middle lobe were lacerated, exposing the clot, which was found to extend across the center of the organ, approaching quite close to the surface of either side and splitting the cerebellum into an upper and lower layer, though there was no evidence of a new-growth.

Supernumerary Urethra.—At a recent meeting of the Académie de Médecine PÉAN (*La Presse Médicale*, June 1, 1895) presented a girl, fifteen years old, who had suffered with dribbling of urine from birth. On examination a prominence was found upon the anterior wall of the vagina, increasing in volume with physical effort, and diminishing in the recumbent posture. Upon compression of this swelling with the finger urine was observed to escape, not from the normal urethra, but from a second opening, about 3 mm. below. A stylet introduced into this opening penetrated into a cavity from which also urine escaped. On occlusion of the lower opening with the finger and compression of the tumor this was reduced in size and the patient felt a desire to pass urine. It thus appeared that there existed a diverticulum of the bladder with a supernumerary urethra, as a result of which, in the absence of a sphincter, there was dribbling of urine. The condition was relieved by exposing and excising the supernumerary parts.

The Nature and the Treatment of Pernicious Anemia.—STOCKMAN (*British Medical Journal*, No. 1794, p. 1085) expresses the opinion that pernicious anemia is not a special disease, but is secondary to numerous exhausting conditions. These induce an initial anemia, which is followed in certain cases by degenerative changes in the bloodvessels. Capillary hemorrhages result and induce an excessive degree of anemia. Some cases are due chiefly to external bleeding, which accounts for the characteristic symptoms and post-mortem appearances. The treatment should, therefore, be based on etiologic considerations.

THERAPEUTIC NOTES.

Methylene-blue for Filaria Sanguinis Hominis, with Chyluria.—FLINT (*New York Medical Journal*, June 15, 1895, p. 737) has reported the case of a well-developed colored man, twenty-two years old, born in the West Indies, engaged as a bar-porter, and residing in the United States for ten months, who presented himself with headache, pain in the sacral region, slight elevation of temperature, and a history of rapid emaciation and muscular weakness. The urine looked like rich milk, being perfectly opaque, with no tendency to precipitation. Its specific gravity was found to be 1.014, its reaction acid. After filtration approximately 2 per cent. of albumin was found present, but no sugar. Upon agitation with ether the urine became perfectly clear. Microscopic examination disclosed the presence of large quantities of finely divided fat-globules, chyle-corpuscles, and a considerable quantity of apparently broken-down matter. No casts were discovered, but there were a few blood-corpuscles. Examination of blood removed from the right ear at 12.30 A.M. disclosed the presence of embryonic filariæ. The patient was given two grains of methylene-blue at intervals of four hours, and on the following night the number of filariæ was found diminished, their movements sluggish, and their bodies, as well as the blood-plasma, to some extent stained blue. The urine lost its milky and turbid appearance, and became perfectly transparent, although deeply stained a characteristic greenish-blue. The treatment was then discontinued, but the urine became milky, and contained filariæ. The patient was again given methylene-blue, and three days later dead and partially disintegrated filariæ were found in the blood, deeply stained with blue. Treatment was discontinued at the expiration of five days, and no further symptoms appeared. Reference is made to the successful use of methylene-blue in the treatment of cases of gonorrhea, as well as malarial fever.

The Treatment of Whooping-cough with Cocain.—WELLS and CARRÉ (*Lancet*, No. 3745, p. 1429) report the treatment of 323 cases of whooping-cough during the autumn and early winter of 1894 with cocain hydrochlorate dissolved in water in doses (gr. $\frac{1}{10}$–gr. $\frac{1}{3}$) based on the standard of a one-grain dose for an adult, three or four times a day, by the mouth. Among the whole number there were two deaths, both in infants under six months of age—one from broncho-pneumonia, and one from persistent vomiting. In no case were evil effects observed. The only prominent manifestation was in some cases slight relaxation of the bowels. The average duration of the disease under this mode of treatment was about three weeks, and in mild cases about a fortnight or less.

PHILADELPHIA.

SATURDAY, JULY 13, 1895.

DEMON-POSSESSION AND ALLIED THEMES.

"THE age of miracles is past" has become a proverb, but like all proverbs it is hardly half-truth. Miracles are occurring all the time if we had but the "eye of faith" to perceive them. In civilized communities they are unknown; they are unnecessary since the spread of the Gospel, say the orthodox—but other lands are more fortunate. China, for instance, still rejoices in them, in the form of genuine "simon-pure casting out of devils" by the humble possessors of the true light, according to the Rev. J. C. Nevins, D.D., whose 500-page volume is that of this article. Probably if we were blessed with the same degree of civilization as "The Flowery Kingdom," we should see similar wonders. Like the *ignis fatuus*, all they require is sufficient darkness to enable their light to be seen. The Reverend Dr. Nevins had no need to go to China in search of such marvels as his pages are filled with; the bottom-lands of Flat Crick and the gullies of the Great Smoky Mounting would have yielded an even richer trove of specimens to the expert miracle-stalker.

The book is a most extraordinary composition. Nothing but the evident sincerity and devoted philanthropy of its author, who gave his whole life to missionary work and literally died in the harness, would enable us to take it seriously. Going to China in early life a complete disbeliever in ghosts, "possession," etc., according to his own statement, he meets so many fearful and mysterious instances of demoniac opposition that he gradually becomes puzzled, and finally a complete believer in the supernatural character of these phenomena. He addresses circular-letters to many of his co-workers and finds them in different stages of the same conviction or bewilderment, and hence comes to the conclusion, "by the inductive of study of phenomena" (deliver us from our own terms!), that the same state of affairs obtains in China now as did in Judea at the dawn of Christianity (which is probably correct), and thereupon boldly proceeds to cast out devils himself and instructs his converts how to do so. He even mentions the particular passages of Scripture found most effective in the connection. He feels himself transported to the days of the Apostles, and refers complacently to the "intimate connection with the progress of Christianity in the neighborhood" of these feats. He declares that "from a large correspondence and personal acquaintance with missionaries in China . . . I have only known two who have expressed positive unbelief in the reality of these possessions."

A number of illustrative cases are given in support of this startling position, and then our "inductive investigator" proceeds to fill up the remaining four fifths of his volume with chapters on remarkable instances of "Possession (of a most familiar order) in India," "in Christian Countries," "Evolution and other Theories," "Spiritualism," "Teachings of Scripture," and "The Literature of the Occult," etc.

The only original part of the book is the small portion of personal experiences and responses to a circular-letter, and is of a most disappointing nature. Beginning with a simple haunted house, which was rented very cheaply as a mission-station on that account, and then the demon driven out by holding evening-prayer, only, however, to enter another house in the near neighborhood. Of this the poor inhabitants not unnaturally complained and came with praiseworthy thriftiness to demand damages therefor from the native mission-teacher. The latter dignitary was equal to the emergency and proceeded at once to the house with a New Testament and a prayer printed on a large card. The

Testament was read, the woman affected promptly restored, the prayer posted on the walls as a preventive. The result, in Dr. Nevins' own words, was that "they were not troubled afterward, though the spirit was heard of trying to gain an entrance into other families in the neighborhood" (!). This is a fair sample of all that follows. Possession by "foxes," by badgers, by snakes (with which latter form we are only too familiar, and also with their evil spirit, whose mystic symbol is C_2H_6O), in Japan and India. The cases in "Christian lands" are even worse, plain hysteria, catalepsy, double personality, etc., some of them being actually quoted from Griesinger's *Mental Pathology*.

Spiritualism and theosophy are neatly brought into line of support and disposed of at the same stroke by being attributed to the activity of genuine evil spirits, to whom the mediums are "sold" in good old medieval style, while even "Dr. Jekyll and Mr. Hyde" and "Khalid" are dragged at the wheels of the argumentative chariot. Of course, the unspeakable W. T. Stead is not forgotten, and when anyone has to cite Mr. Stead as evidence it is a severe reflection upon the direness of his logical extremity.

In all seriousness and with a genuine respect for the author's devotion and evident sincerity, it seems wellnigh incredible that any man of his intelligence and education could extract the smallest atom of solid conviction from such a frothy mass of self-evident ghost-stories and fairy-tales, or could even relate them with seriousness.

The only way it can be accounted for is the influence of a life-long exposure to an atmosphere of belief in them. The instances in themselves are trivial, but the impressiveness of a vivid acceptance and dread of them by absolutely everyone by whom one is surrounded is overwhelming. Even Rudyard Kipling, that hard-headed Philistine of the twentieth century, has caught the infection and reveals traces of a belief that "other influences are at work in India," which is more than half genuine. The unconscious influence of environment is far greater than we imagine. How quickly one picks up the accent and idioms of a people by living among them, and habits of thought are wellnigh as infectious as habits of speech. There seems little doubt that constant association with the insane favors the development of eccentricities in their attendants, and even physicians. The moral tone of great criminal lawyers is said often to sink nearly to the level of that of their clients. And it would seem that even the missionary is unconsciously tinged by the heathenism among which he spends his life.

This work emphasizes a truth that has been growing in importance and recognition, that is, not only should our missionaries be medically educated, but they should have practical and clinical courses in mental diseases. A course of scientific study, however limited, would teach the differential diagnosis between "demon-possession" and mental abnormalism. Psychiatry kills superstition.

THE TREATMENT OF SNAKE-POISONING AND THE ESTABLISHMENT OF IMMUNITY BY MEANS OF THE BLOOD-SERUM OF IMMUNIZED ANIMALS.

THE question of the treatment of snake-poisoning has at different times engaged the brightest minds in medicine in clinical research and experimental investigation, with the hope of discovering an antidote for this fatal form of intoxication. A new impetus has been given the subject by the recent developments in connection with the treatment of infectious diseases by means of the blood-serum of animals rendered immune through gradually increased dosage with virulent cultures of the respective micro-organisms. In a line with these observations are the results of an experimental inquiry undertaken by Professor Fraser[1] and embodied in a communication presented at a recent meeting of the Royal Society of Edinburgh. This paper dealt with the consideration of methods for rendering animals immune to the venom of various poisonous snakes, and of the use of the serum of such animals for transmitting immunity and also of combatting the effects of snake poisoning.

Having determined the lethal dose of the respective venoms for lower animals, these were treated with a succession of gradually increasing non-lethal doses, until the actual minimum lethal dose was determined. The treatment was then continued until a dose far in excess of the ordinary lethal dose was tolerated without serious reaction or injury on the part of the animals. So successful were the experiments that, notwithstanding the various natural difficulties, it was possible to give rabbits by subcutaneous injection as much as ten, twenty, thirty, and even fifty times the minimum lethal dose without causing obvious symptoms of poisoning, the only observable

[1] British Medical Journal, No. 1798, p. 1339.

phenomena being a rise in bodily temperature, continuing for a few hours, and loss of appetite, with decline in bodily weight. Not only was it possible thus to immunize animals against a specific venom, but it further appeared that animals thus immunized are capable of resisting the lethal action of other venoms, though in less degree. It was incidentally discovered that the protection thus conferred lasts for, at least, a considerable period of time, even when the last protective dose was not a large one. The explanation of these remarkable facts is believed to reside either in the production in the body by the influence of the venom of productive substances, or in the presence of these substances as an actual part of the venom itself, gradually accumulating with repeated administrations, whereas the lethal and toxic constituents of the venom are more rapidly destroyed or eliminated.

Having thus succeeded in inducing a high degree of protection in animals against the toxic effects of serpent's venom, the blood-serum of such immune animals was passed through a Chamberland filter and placed over sulphuric acid in the receiver of an air-pump. A perfectly dry and easily pulverizable solid was thus obtained, which could be kept unchanged for probably an indefinite length of time, and to which the name "antivenene" has been given. Four series of experiments were undertaken in which (*a*) the venom was mixed outside of the body with the antivenene, and the mixture injected under the skin of the animal; (*b*) the venom and the antivenene were injected almost simultaneously into opposite sides of the body; (*c*) the antivenene was injected a considerable time before the venom; (*d*) the antivenene was injected thirty minutes after the venom. The results of these experiments go to show that the blood-serum (antivenene) of animals protected against large doses of snake-venom is capable under varying conditions of administration of preventing lethal doses of the venom of the most poisonous serpents from producing death in non-protected animals. For the actual application of the antivenene to the treatment of snake-poisoning in man an endeavor is being made to obtain the large quantity that is requisite from a horse now receiving considerable lethal doses of cobra-venom, and from the same source it is hoped that a sufficient quantity will be obtained to allow of the examination of the chemic properties of the antivenene, with the object of discovering the constituents by which the antidotal effects are produced.

Results of a confirmatory character have been obtained by Dr. Calmette,[1] the head of the bacteriologic station at Saigon, China, whose methods were analogous to those of Professor Fraser. He, too, found that the venom of different animals is capable of conferring general immunity, though in varying degree. Rabbits rendered immune to snake-venom proved also resistant to abrin, while animals protected against abrin acquired a certain degree of immunity to snake-poisoning, diphtheria, ricin, and anthrax. In immunized animals injection of the venom is attended with hyperleukocytosis, while in untreated animals hypoleukocytosis develops. It was further discovered that snake-poison is rendered innocuous by admixture with a solution of calcium hydrochlorid or of gold chlorid.

The mortality from snake-poisoning in some parts of the world, notably in India and Australia, is very considerable, and a great saving of life must be effected by the conduct of Professor Fraser's investigation to a successful termination. We have here a further illustration of the yet not sufficiently recognized fact that the solution of no scientific problem is without practical bearing and utility. Even empiricism must have some sort of scientific basis, and the more strictly the practice conforms to the science the more permanent and successful will it be.

EDITORIAL COMMENTS.

The Treatment of Diphtheria with the Antitoxin.—Favorable reports of the use of the antitoxin in the treatment of diphtheria continue to be published, but it is observable that the latest are couched in cautious and conservative language. The data appear not yet sufficient for a final conclusion, but it cannot be denied that the preponderance of sentiment, as well as the weight of statistics, tends to sustain the hope held out as to the efficacy of the antitoxic serum.

One of the most interesting and important contributions to this subject has recently been made by LEICHTENSTERN and WENDELSTADT (*Münchener medicinische Wochenschrift*, 1895, No. 24, p. 553), in which they present the results of a careful analytic study of cases of diphtheria coming under observation during a series of years at the Augusta Hospital at Cologne. This article is to be commended for its judicial tone and for the dispassionate manner in which it deals with a subject concerning which much has been written within a short time, and even more enthusiasm has been displayed. While expressing themselves in favor of the utility of the new remedy, they point out its limitations and call attention to certain fallacious conclusions that have been reached without mature deliberation.

The study embraces a series of 123 cases treated with

[1] Vide British Medical Journal, p. 1339.

the antitoxin during 1894–95. With this they compare eleven series of similar numbers seen consecutively before, from 1892 to 1894. During the period preceding the use of the antitoxin the average mortality of all cases was 30.9 per cent. (with a minimum of 25 and a maximum of 39), while during the antitoxin-period it fell to 20.3 per cent.—a considerable reduction in the mortality.

During the antitoxin-period tracheotomy was required in 30 per cent. of the cases, with a mortality of 43.2 per cent., while in the previous periods operative interference was required in 32 per cent. of the cases (from 21 to 38.3 per cent.), with a mortality of 64 per cent. (from 56 to 76 per cent.). It is thus clear that while the use of the antitoxin exercised but little influence upon the proportion of cases in which tracheotomy was required, it caused a material reduction in the mortality among cases operated upon.

Among the 70 per cent. of cases not requiring operation during the antitoxin-period there were 10.4 per cent. of deaths, while among the 68 per cent. of similar cases (from 61 to 79 per cent.) seen previously, death occurred in 15 per cent. (from 9.2 to 27 per cent.). Both the proportion of cases in this group and the mortality were thus approximately the same, whether the antitoxin was used or not.

The net result of these figures is that the diminution in the mortality of cases of diphtheria treated with the antitoxin is attributable to the number of cases saved in which tracheotomy is required. Special attention is called to the fact that no evil results were observed from the use of the antitoxin, and the claim is sustained that the agent is totally innocuous.

The Treatment of Tetany with Thyroid Extract.—One cannot avoid being moved with admiration of the consecutiveness of the steps—so like the solution of a mathematic problem—by which was reached the conclusion that led to the employment of preparations of the thyroid gland in the treatment of myxedema and allied conditions; and the success that has been attained has quite opened a new field in therapeutics. Of the diseases related to or dependent upon disordered function of the so-called ductless glands we have much to learn, and such knowledge must surely bring enlarged therapeutic resources. Thyroid therapy has shown itself capable of a useful influence not only in myxedema and cretinism, but also in some cases of exophthalmic goiter, in some of akromegaly, and in some of psoriasis. To this list we may now add tetany, which, in some cases at least, further observation may show to be a thyroid disease. BRAMWELL (*British Medical Journal*, No. 1796, p. 1196) has made a number of interesting observations upon the employment of thyroid extract in the treatment of tetany. In the case of a patient in whom tetany had developed after removal of the thyroid gland, and who was being treated with small doses of thyroid extract, he advised that the remedy be pushed in much larger doses. In the course of a short time, the tetany and other symptoms disappeared and the patient made a rapid and complete recovery. Expression is given to the opinion that operative tetany is merely one manifestation of acute myxedema resulting from arrest of thyroid excretion, and of this opinion the experience reported is considered to be confirmatory. On another occasion, on being consulted about a boy of eight years, who had previously been under his observation for tetany, BRAMWELL advised the internal administration of thyroid extract, with the result that in the course of three weeks the improvement seemed "almost phenomenal." The attack had existed for nearly a year-and-a-half and had been variously treated with arsenic, chloral, antipyrin, bromid, cod-liver oil, etc. The child had had whooping-cough and influenza, and several months before the onset of the tetany had been knocked down by swinging jute. It has been pointed out that cold seems to aggravate tetany and to induce relapses, and that the disease is much more frequent in winter and spring than in summer and autumn, and these facts are viewed as denoting another important point of relationship between tetany and myxedema, for it has been shown also that cold predisposes to the production of myxedema. On account of the association of tetany in infants with rickets and laryngismus stridulus, it is further suggested that thyroid extract may also prove of therapeutic utility in these two conditions. Should this utility be demonstrated, the conclusion would be reasonable that these several disorders are attributable to a deficiency or a modification of the thyroid secretion.

The Index Medicus.—Every medical man interested in the welfare and progress of both his science and his art will have learned with deep regret of the unwillingness of Mr. George S. Davis to continue longer the publication of the *Index Medicus*. It now remains to be seen whether the profession will permit such an important, we may say indispensable, record of current literature to die or will unite in some concerted movement to sustain and carry on the great work. As a matter of fact, the duty really belongs to the government, but in default of such a satisfactory and logical disposition of the matter it devolves upon the medical body to advance the necessary means and provide the requisite support.

The subject is one that concerns not only the profession in America, but medical men throughout the world. In recognition of this fact the resident librarian of the Royal Medical and Chirurgical Society of London urges in the *British Medical Journal* scientific societies and scientific workers to subscribe to a fund for the continuance of the *Index*. He proposes that every English medical society should annually contribute at least two guineas for the support of the *Index*, and believes that sufficient could additionally be obtained from individual medical men to make an English guarantee-fund of not less than £400.

Dr. C. E. Sajous, of Philadelphia, sends from Paris to the editor of the *New York Medical Journal* twenty-five dollars, and suggests that two-hundred subscribers agree to contribute an equal sum annually. Mr. Davis has expressed himself in sympathy with this movement and offers to undertake the publication of the *Index* again, without profit or remuneration, provided a guarantee-fund be established that would secure him as publisher against loss. Should a surplus be realized it would be divided pro rata among the guarantors. We hope these efforts to save the *Index* will succeed beyond peradventure. The medical profession cannot afford to have them fail. We commend every one interested—and all should be—to communicate with Mr. Davis at Detroit.

Live-stock Sanitation in Pennsylvania.—Act No. 66, of the Pennsylvania Legislature, approved May 21, 1895, provides for a Live-stock Sanitary Board, whose purpose it shall be to endeavor to control and suppress "dangerous, contagious, or infectious diseases of domestic animals." The Board is to consist of the Governor, the Secretary of Agriculture, the State Dairy and Food Commissioner, and the State Veterinarian, and is empowered to enforce and regulate quarantine of animals, destroy them if deemed necessary, and regulate the movements of their products. The Board is authorized at any time to enter any premises, farms, fields, pens, abbatoirs, slaughter-houses, buildings, cars, or vessels where any domestic animal is at the time quartered, or wherever the carcass may be, for the purpose of examination. It shall also take such proper measures as may be deemed necessary for the protection of the milk-supplies from contamination. If this Board will carefully perform the duties with which it is charged, we may speedily hope to see a better milk-supply in this State, and perhaps some solution of the vexed question of the relation of tuberculosis in cattle to human tuberculosis.

The Number of Physicians and Surgeons in the United States.—According to the Bulletin on "occupations" of the eleventh census, just issued, there were in the United States, in the year 1890, 104,803 physicians and surgeons, or about 1 to every 600 of the population. The total number of wage-earners of all occupations is placed at 22,735,661. There were 89,630 lawyers, 88,295 clergymen, 58,090 nurses and midwives, 17,498 dentists, and 9900 undertakers.

SELECTION.

THE AMERICAN MEDICAL ASSOCIATION AND PATENT MEDICINES.

THERE is no doubt that the members of the medical profession, as a class, are opposed to patent medicines. The encouragement these remedies occasionally receive from physicians is usually due to carelessness or inexcusable ignorance.

The American Medical Association, at its May meeting in Baltimore, placed itself clearly on record in regard to this subject, and in a manner that is highly commendable. It involves a much-needed reform in the Association's journal, as is shown by the following extract from the report of the Board of Trustees concerning that journal:

"During the year no advertisements of secret remedies have been accepted that were not accompanied by a formula, but to still further comply with what appears to be the desire of a large number of those interested in the success of the *Journal*, the editor, with the termination of present contracts, has been instructed to accept no advertisements of medicinal preparations, the proprietors of which do not give a formula containing the official or chemic name and quantity of each composing ingredient to be inserted as a part of the advertisement."

This report was adopted with considerable enthusiasm, and we think the Board need not have used the guarded language it did by saying they proposed to "comply with what *appears* to be the desire of a *large* number," for the sentiment of those present not only *appeared* to be, but actually *was unanimous*.

As many of the advertisements in the above-mentioned journal, as well as in many other medical journals, have long been a standing disgrace to the profession they represent, we, more than a month after the meeting, made an examination of the advertising pages of the Association's *Journal*, but were unable to notice that any decided change had taken place. We, therefore, concluded that the advertisers' contracts had not expired.

There were, however, a number of advertisements in which the formulæ were given, and the conclusion was that their contracts had expired, or else they were preparing to renew.

Two of these formulæ were so unique, and at the same time so interesting, that we venture to enlighten our readers by reproducing them here, as follows:

"ANTIKAMNIA.

"*Formula.* A combination of coal-tar derivatives of the series C_nH_{2n-6}, into which the amines have entered, forming the various amido-compounds. Antikamnia has as its base the derivatives of the amido-benzoles, so combined as to obviate the bad effects caused by many of this series of organic bodies when administered alone."

"CAMPHO-LYPTUS.

"*Composition.* Eucalyptol, campho-thymic acid, hydrous chloral."

No possible good can result from publishing such formulæ as these. They are simply ridiculous, and the *Journal of the American Medical Association*, by admitting them, lays itself open to the possibility of being considered the most "gullible" medical journal on the face of the earth.

There is no secret about the faculty necessary to decide what should be admitted. We could name a dozen members of the medical profession who possess that inborn knowledge which would enable them to decide almost in a moment on the admissibility of an advertisement. The result, however, would be such a "clean sweep" in the advertising pages of the Association's *Journal* as to be apparent to the most casual reader.

There is another lesson to be derived from these so-called formulæ. We have heard a great deal in the past few years about legislation to control the manufacture and sale of patent medicines, and nearly all of the suggestions are based on the publication of the formula on the label. But the experience of the American Medical Association shows us that it will be necessary to define whall shall constitute a formula.—*American Journal of Pharmacy*, July, 1895.

REVIEWS.

PERSONAL REMINISCENCES AND RECOLLECTIONS OF FORTY-SIX YEARS' MEMBERSHIP IN THE MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA. By SAMUEL C. BUSEY, M.D., LL.D., etc. 8vo., pp. 373. Washington, D. C., 1895.

THIS is the most interesting volume of medical *ana* that we have seen for a long time. The author tells us that he has not attempted to write an autobiography, but he was a conspicuous actor in many of the ethical con-

troversies which he describes, and incidentally gives a good deal, though not enough, of information about his own personality.

Beginning the study of medicine in 1845, in the old-fashioned way, by entering the office of an old-fashioned doctor, he learned enough in his first year to know that private pupilage in an office in Georgetown, without a book more recent than 1820, and with only two or three rusty scalpels and a pair of tooth-pulleykins, did not supply the opportunities he desired, and therefore in 1846 he came to Philadelphia and entered the office of George B. Wood as a private pupil.

His chapter on the life of a student of medicine in those days, including a description of the methods of Dr. Wood with his private pupils, contains some graphic pictures, and makes it clear that such pupils had to study. He commenced practice in Washington in 1848, and the old residents of that city must enjoy his description of the condition of things there at that time. There were but two streets that were even partly paved, garbage was thrown into the alleys, and swine were the privileged and protected public scavengers. To jostle against or drive over one of these municipal functionaries when out on his tour of sanitary inspection insured a cash penalty or brief servitude in the workhouse.

A large part of the book is occupied with the history of the Medical Society of the District of Columbia, of which the author has twice been President. Special attention is called to the active part taken in the work of the society in its early days by medical officers of the army and navy. One chapter is devoted to the disturbances that arose in connection with the proposition, in 1869, to admit physicians of African descent to membership in the Medical Society, disturbances that extended to the American Medical Association, and that lasted for several years.

Another chapter treats of some of the effects of the rule of the Medical Society that its members shall not consult with physicians not members of the society, and of some of the trials for violations of ethics, of some members of the society. This will be curious reading fifty years hence. Dr. Busey says, "There remain some regulations which fall short of the more advanced conception of medical ethics. These, at least some of them, are, perhaps, justifiable, in view of the peculiar environments of the profession in the District of Columbia. The absence of a medical practice law makes it necessary to retain the limitation of consultation to membership, and to those, not members, to whom it has been legally extended by definite designation. The District of Columbia is now the common rendezvous of the impostors and charlatans driven from the States by the enactment of medical practice laws, and some sharp and incisive mark of distinction between such refugees, both of the itinerant and permanent class, has become of imperative necessity, as well for the protection of the community as for the maintenance of the honor and dignity of a scientific profession. The retention of a fee-bill schedule, with its minimum and maximum charges for every distinct and definite professional service, partakes too much of the ill-advised rules of trades unions, which demand the same wages for the incompetent as for the skilled artisan; offers protection to the ignorant, in that it holds his services equal in value to those of the learned and skilled, and invites a class of unfit men to sneak into a benevolent and scientific profession who could not earn a decent livelihood as ordinary mechanics. The regulation in regard to fees and consultations, as did the organization of the Medical Society in 1819, and Medical Association in 1833, grew out of the necessity of protection from the wrongs, injuries, and disreputable practices of the horde of irresponsible and ignorant charlatans that infested and desecrated the infant city; and it is probable they will be continued in operation as long as such protection and distinction are made obligatory by the failure of Congress to enact a suitable medical practice law."

Dr. Busey has made a substantial contribution to the history of medicine in this country, and his book should be of interest to all members of the medical profession.

The Transactions of the Sixteenth Annual Meeting of the American Laryngological Association for the Year 1894. New York: D. Appleton & Co., 1895.

This volume contains many valuable and instructive papers. Among those especially interesting is the paper by Dr. Jonathan Wright, of Brooklyn, on "Papillary Hypertrophy of the Nasal Mucous Membrane, Compared with a True Papilloma." This is of especial interest from a diagnostic and pathologic standpoint. The accompanying plates are clear and well defined. There is an interesting report by Dr. Charles M. Shields of a case of a foreign body (cocklebur) in the larynx and its removal intact by means of Schrötter's tube-forceps. Casselberry has an admirable paper showing the association of nasal polypus with ethmoiditis, and recommends treatment by resection of the middle turbinated body. French makes some valuable observations as to results in cutting operations on the nasal septum, showing that with proper care the healing process goes on rapidly; also that there is little danger of weakening the septum. The case of compound follicular odontoma reported by A. W. de Roaldes is interesting from a pathologic standpoint, as it is an extremely rare condition. The accompanying plates are instructive. Dr. Harrison Allen's paper, "Demonstrations of Skulls, Showing the Effect of Cretinism on the Shape of the Nasal Chambers," is one of the most valuable papers contributed.

Addresses, Papers, and Discussions, Section on Surgery and Anatomy at the Forty-eighth Annual Meeting of the American Medical Association, 1894.

This volume contains much of interest and value. John B. Roberts contributes an interesting paper, in which he combats the operative frenzy that has seized upon so many surgeons during the past few years. Wyeth discusses inoculations with septic or toxic agents in the treatment of malignant tumors, and concludes that sarcoma may be cured by septic infection. Allis contributes an able article in which he favors treating fractures of the lower end of the humerus in extension.

Amongst numerous interesting articles we note especially: Conner upon fractures of the lower end of the humerus; Deaver upon vesical tumors; Gaston on

anal fistula; Bonwill on the surgical engine; Belfield on prostatic enlargement; Lovett on the operative treatment of joint-tuberculosis; and Reginald Sayre on the conservative treatment of tuberculous joints.

The publication of these *Transactions* in a book small enough to be conveniently handled is commendable.

FORMULAIRE DES MÉDICAMENTS NOUVEAUX ET DES MÉDICATIONS NOUVELLES POUR 1895. Par H. BOCQUILLON-LIMOUSIN, pharmacien de 1re classe, lauréat (medéille d'or) de l'école de pharmacie de Paris. Introduction par le Dr. Huchard, médecin des hôpitaux. Sixième edition, 1 vol. in 18de 340 pages.

THE 1895 edition of this familiar work contains a large number of new articles, among which may be noted the following: Alangin, Alphol, Antipyonin, Bromethylformin, Cathartenic Acid, Chloralose, Cristallin, Diaphtol, Diiodoform, Ferratin, Glycozene, Iodoformin, Medicated Milks, Loretin, Lycetol, Menacin, Paraform, Resol, Salumin, Serotherapy, Pulmonary Juice, Tannal, Thioform, and Vasogene. There are also here contained a large number of colonial and exotic plants that have been recently introduced into therapeutics, and which have not, as yet, found place in any other formulary, however recent. The book is a valuable little aid to practical medicine up to date.

THE RETROSPECT OF MEDICINE. A Half-yearly Journal Containing a Retrospective View of Every Discovery and Practical Improvement in the Medical Sciences. Edited by JAMES BRAITHWAITE, M.D. Lond. Volume 110. July–December, 1894. (Issued January, 1895.) London: Simpkin, Marshall, Hamilton, Kent & Co., Limited. Edinburgh: Oliver & Boyd. Dublin: Hodges, Figgis & Co.; and Fannin & Co. Leeds: W. Brierly, Bond Street.

WE have only to repeat concerning the one hundred-and-tenth volume of Braithwaite's Retrospect the good opinion we have uniformly expressed of its predecessors. The judgment exhibited in selection, the preservation of the exact language of the authors quoted, the good index, and the wide range of reading represented by the journals cited, render it one of the best books of reference to current literature in the market.

TEMPERATURE-CHART. Prepared by D. T. LAINÉ, M.D. Copyrighted by W. B. Saunders, Philadelphia.

THIS chart is evidently intended as a record for cases of fever treated with cold baths according to the method of Brand. Provision is made for thirty-two observations of temperature, pulse, and respiration in the course of twenty-four hours, as well as for notes upon the excretion of urine, the evacuation of the bowels, the amount of food, and other matters that may be considered important or interesting. Upon the reverse side of the sheet is a description of the method of Brand for the treatment of typhoid fever.

THE YEAR-BOOK OF TREATMENT FOR 1895. A Critical Review for Practitioners of Medicine and Surgery. Octavo, pp. 490. Philadelphia: Lea Brothers & Co., 1895.

THIS issue of the *Year-book* maintains the reputation established by previous issues. Its contents naturally do not include everything new that has developed during the past year, but the attempt has been made to select that which is practical and promises to be of permanent value, and omit that which appears unimportant. The work has been done by twenty-three contributors whose names are well known in English medical literature. The name of the editor, however, does not appear.

ATLAS UND GRUNDRISS DER OPHTHALMOSKOPIE UND OPHTHALMOSKOPISCHEN DIAGNOSTIK. Mit 5 Text und 102 Farbigen Abbildungen auf 64 Tafeln. Von DR. O. HAAB, Professor an der Universität und Direktor der Augenklinik in Zürich. München, 1895. Verlag von J. F. Lehmann.

THIS excellent manual of ophthalmoscopic pictures will be welcomed by all ophthalmologists, by reason of the convenient size of the book, and because of the large number of capital illustrations of typical diseases of the eye-ground. An introduction treating of ophthalmoscopy is noteworthy, and a page of explanatory text accompanies each plate.

SOCIETY PROCEEDINGS.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Seventeenth Annual Meeting, held at Rochester, N. Y., June 17, 18, and 19, 1895.

FIRST DAY—JUNE 17TH.

DR. JOHN O. ROE delivered the President's Address, the subject of which was

THE RELATION OF DAMP AIR TO DISEASES OF THE UPPER AIR-PASSAGES, ESPECIALLY IN THE LAKE REGION.

He pointed out that no one region is good for all ailments. That beneficial for respiratory affections is generally bad for biliary troubles, and *vice versa*. The effect of any climate is due partly to its direct influence on internal organs and partly to its indirect influence upon the habits of the individual. In the Lake region diseases of the air-passages are very common, while the biliary disorders are comparatively infrequent. The region is characterized by great humidity, with sudden temperature-variations and a low mean animal temperature.

The amount of watery vapor in the atmosphere depends largely on the soil. It is relatively small where the soil is sandy and porous and drains quickly, even after heavy rainfalls; and it is relatively large where the soil is heavy, with an underlying stratum of clay. In the Lake region both soils are found. Cultivated soil signifies less moisture than uncultivated. The Lake region soil is highly cultivated and in so far beneficial in reducing the atmospheric humidity. The temperature is affected by the cold air that sweeps down from the great lakes. The changes of temperature are frequent and rapid. The early warm days of spring are followed by chilling blasts from the North. The amount of cloudiness is considerable, averaging six-and-one-tenth days out of ten for the past twenty-five years. The average

rainfall of the Rochester district is 27 inches, the mean annual temperature 40°. Other localities possessing the same general characteristics may be free from the cold-air currents and thus present a very different resulting climatic condition.

Damp air is injurious to the body in that it checks insensible perspiration, and hence there result endosmosis through the mucous membrane and a checking of elimination, both of which lead to turgescence, hyperemia, and hypernutrition. The nose bears the brunt of this bad influence, owing to both its direct exposure and its normally abundant vascular supply.

A peculiarly pernicious habit is that of sleeping in cold weather with the window wide open. The body is subjected to the influence of damp air at a time when its natural reactionary resistance is low, and the patient sleeps in a temperature that would be undesirable if he were awake. Hence we have that frequent naso-pharyngeal tumescence, with its characteristic symptom-group, known as the "American Disease."

We must learn to drain our lands and houses thoroughly and how properly to ventilate our sleeping-rooms.

DR. E. FLETCHER INGALS, of Chicago, read a paper on

DESICCATED THYROIDS IN GOITER.

He related that during the past fifteen years he has treated eighty-one cases of bronchocele and exophthalmic goiter. He gave potassium iodid thrice daily in doses of from five to ten grains. If no improvement resulted in two or three weeks, he gave tincture of iodin in doses of from five to twenty-five drops in capsule, followed by a large draft of water, or, in connection with this, injections of from 3 to 5 per cent. solution of carbolic acid in glycerin and water, from twenty to fifty minims being injected once a week.

For the past four years he has used the thyroid preparations and the desiccated preparations in his last six cases of goiter. Six grains of this represent one entire gland. All of his cases, except one, are still under treatment, and had been previously treated according to the old method. In addition, Dr. Ingals has obtained reports of forty-four cases treated by other physicians. Of one series of twenty-five, all but seven were improved. The neck was reduced in size, but the remedy seemed to cause headache in 30 per cent., dizziness in 37 per cent., and increasing rapidity of the pulse in 25 per cent. Out of the whole number of fifty cases the size of the neck was reduced in thirty-eight. Out of seven cases of myxedema improvement was noted in five. In addition to the unpleasant symptoms noted previously, there have also been observed trembling, backache, weakness, nausea, loss of weight, and in one instance uterine contractions.

Dr. Ingals summarized his conclusions as follows:

1. Thyroid preparations show powerful physiologic effects on the nervous and circulatory systems. These symptoms result from the daily use of from one-and-one-half to two glands, and there is reason to believe that too large quantities might produce fatal results.

2. The desiccated preparations are best. Internal use yields as good results as does hypodermic injection, and the initial dosage of the preparations should be two grains, which may gradually be increased to eight.

3. The effect on bodily weight is uncertain, varying not only in different patients, but also at different times in the same individual. Alleged disturbances from the remedy may be due to incidental digestive disorders.

4. The remedy is useful in myxedema.

5. In non-exophthalmic cases the cardiac condition is sometimes aggravated rather than relieved. Cystic conditions are not affected.

6. Outside of the foregoing conditions there is none in which thyroid therapy promises any good results.

In discussing this paper, DR. E. L. SHURLY, of Detroit, expressed disappointment at his own results in some eighteen or twenty cases subjected to thyroid treatment. He mentioned the case of a boy from whose neck a large thyroid was removed by operation. The patient seemed to develop somewhat, but did not grow in size, and three or four years later he was mentally apathetic and had a peculiar piping voice. Laryngeal examination showed normal movement of the arytenoids and the bones, but the latter did not assume the normal tension in phonation. Thyroid feeding for two years improved the throat-condition, though previous hypodermic use of the remedy had been without effect. He would condemn the total extirpation of the gland in view of the bad condition that may follow such a radical procedure. The leaving of a small portion seemed to prevent such an untoward result.

DR. W. E. CASSELBERRY, of Chicago, had treated one case of exophthalmic goiter with fresh thyroid gland, with improvement, but not cure. He alluded to a recent paper by Paul Bruns, who had found that the younger the patient the better the result. Thus of the cases in the first decade of life all were cured; in the second decade, 75 per cent. were cured; but after this age the results were less satisfactory, and after the fortieth year decidedly unsatisfactory.

DR. INGALS, in closing, said that the drinking of distilled water should be insisted upon in this disease, as bad water seemed to be in many instances the distinct etiologic factor.

DR. W. E. CASSELBERRY read a paper on

ELECTROLYSIS BY A CURRENT-CONTROLLER FOR THE REDUCTION OF SPURS OF THE NASAL SEPTUM,

and described a special apparatus to be used with the Edison (continuous) current. The ideal electrolytic current should be one of moderately high tension (voltage) He employed the bipolar method in *séances* of from six and of comparatively low current-strength (ampèrage), to eight minutes and with from fifteen to forty milliampères. His needles were made of irido-platinum. His personal experience consisted of ten cases, which, for this purpose, he divided into three types:

1. Strictly cartilaginous spurs. These can be removed by electrolysis, but the method is more tedious and less brilliant than other procedures. It is free from hemorrhage, but is not a universal substitute for time-honored surgical methods.

2. Spurs made up of both cartilage and bone. These will reduce in size in proportion to the amount of cartilaginous element present.

3. Spurs wholly bony. These cannot be reduced by electrolysis. Needles will not penetrate them, and the process will not resolve bone.

4. Deviations cannot be remedied by this method.

DR. W. H. DALY, of Pittsburg, condemned electrolysis as a mere theory rather than a fact. He prefers the usual surgical procedures, especially the trephine driven by the De Vilbiss motor. He contended that Dr. Casselberry's apparatus, moreover, could not be used with the customary alternating current.

DR. JONATHAN WRIGHT, of Brooklyn, thought the method had a field of usefulness in cases in which pulmonary tuberculosis or other debilitating condition was present and a serious result might follow the usual surgical methods.

DR. INGALS said that the soft anterior septal spurs could be removed by the galvano-cautery point heated to whiteness.

DR. S. HARTWELL CHAPMAN, of New Haven, thought Dr. Casselberry's apparatus faulty in that it did not subdivide the current finely enough to prevent shock when used in the nose.

DR. A. B. THRASHER, of Cincinnati, inquired if the bipolar method was less painful than the monopolar.

DR. CASSELBERRY replied that it was. He admitted the force of Dr. Chapman's criticism and hoped to remedy this defect of his apparatus.

DR. GEORGE B. HOPE, of New York, read by title a paper entitled

IS ACUTE TONSILLITIS IN ANY WAY DEPENDENT ON THE RHEUMATIC STATE?

He took the ground that the theory of acute tonsillitis being very generally attributable to an underlying rheumatic or gouty diathesis has not been substantiated by clinical observation. It was contended that patients subject to attacks of tonsillitis do not commonly give a history of rheumatism, proximate or remote, and that, on the other hand, the rheumatic individual rarely suffers from tonsillar inflammations. It is noteworthy that in later life the tonsils become less and less disposed to acute attacks, while the rheumatic tendency becomes more confirmed. Moreover, as a local acute manifestation, rheumatism selects a sero-fibrous rather than a muco-fibrous or lymphatic structure, as the tonsil. It was also maintained that suppurative peri-tonsillitis is clearly infectious and frequently a sequel of intranasal operations.

The conclusion was reached that the favorite anti-rheumatic treatment, as guaiac or the salicylates, addressed to the condition is either erroneous in practice or acts independently and by methods not clearly understood. Such remedies should not be considered specifics, but should be used in accordance with the varying conditions of the subject. Moreover, it has not been proved that the treatment does abort or mitigate the course of the disease.

Various new instruments were then exhibited by members of the Association, and the following papers were read by title:

FOREIGN BODIES IN THE ESOPHAGUS,

by DR. HARRISON ALLEN, of Philadelphia;

THE INFLUENCE OF CHRONIC DISEASES OF THE THROAT UPON CERTAIN DEFECTS OF SPEECH,

by DR. D. BRYSON DELAVAN, of New York.

SECOND DAY—JUNE 18TH.

DR. JOHN A. FARLOW, of Boston, reported

TWO CASES OF LIPOMA.

One was in a boy, aged two years, who presented a lipoma of the inner side of the right cheek. Nothing had been noticed till one day the child seemed to have a little blood in his mouth. Examination showed a reddish lobulated growth, soft and movable, looking like parotid glandular tissue, and pedunculated, just opposite the mouth of Stenon's duct. Removal was effected with the cold-wire snare, and was unattended with hemorrhage. The second case occurred in a man, aged sixty-six years, who had had a tumor in his mouth for fifteen years. Seven years previously a "piece was removed with scissors." When first seen the man presented a mass in the front part of the mouth, but evidently attached a good ways back. He was obliged to wrap a piece of cloth around it and hold it away from the teeth to prevent injuring it. Suffocative attacks occurred from a piece of the mass falling down between the vocal bands into the trachea. With the cold-wire snare and scissors quite a large piece was removed. The patient was then lost sight of, but returned a year or so later with recurrence of the growth and return of the former symptoms. With the galvano-cautery snare the entire mass, which was just above and in front of the right arytenoid, was now removed.

DR. FARLOW made

SOME REMARKS ON THE REMOVAL OF THE TONSILS,

dealing with the choice of operative methods. It is necessary first to break up adhesions between the faucial pillars. Then if there are present the usual large projecting tonsils of childhood, with adenoids in the vault, anesthesia should be secured, the tonsils removed with the cold-wire écraseur, and the adenoids taken out. All this would be easy enough if large tonsils always occurred in large mouths. Unfortunately, however, they frequently occur in small mouths with narrow jaws. A special instrument was exhibited which is a modification of Hooper's snare, having a straight canula and a reinforcement of weak points. The wire is the usual No. 5 or No. 7 piano-wire. The tonsil should be pushed out from its bed by external pressure, and can, as a rule, be very quickly removed. Cocain is applied if no adenoids are to be removed, and ice is used freely after the operation.

Dr. Farlow has also had good results with Ruault's punch-forceps, though they seem very large and clumsy, and their use occasions some pain; also with Hartmann's conchotome, though it was devised for intranasal work. The latter is especially serviceable in getting out the deep-seated tonsillar tissue high up between the faucial pillars. He also uses small curved knives to cut up the surface of the tonsil so as to render the tissue available for seizing with the forceps. The galvano-cautery he has found very tedious.

In discussing the paper, DR. F. H. BOSWORTH, of New York, said that the more we regarded the tonsil as only diseased tissue the more rational would be our treatment of these cases. He had learned to expect possible bleeding whenever he cut into lymphoid tissue. In children this did not occur. Large rounded tonsils

could easily be guillotined, but the removal of those spread out, and with adhesions to the faucial pillars, was a more difficult matter. These must be dug out, and no one instrument will answer for every case.

DR. INGALS had seen bleeding from small tonsils whose removal seemed indicated, but which were not large at the time of operation. Cocain did not anesthetize to any great extent, and it did promote bleeding.

DR. CARL SEILER, of Philadelphia, alluded to the canalization of the vessels in the indurated tissue as a cause of bleeding. He believed that the long diameter of the tonsils was horizontal rather than vertical, a fact overlooked by our instrument-makers.

DR. J. C. MULHALL, of St. Louis, laid stress upon the necessity of breaking up all adhesions between the faucial pillars.

DR. DALY thought that more bad surgery had been done on the tonsils than on any other part of the body. They form no part of the normal throat. The ordinary Mackenzie tonsillotome only partially accomplishes the desired result. We must finish by trimming with the knife and forceps. He had had four or five cases of alarming hemorrhage.

DR. CASSELBERRY believed that children do bleed severely at times, and whenever removing the tonsils with the guillotine always has a reliable galvano-cautery ready to use if hemorrhage occurs. It is difficult to separate the pillars, but if he can get the muscular element of the latter free he does not mind if he sacrifices a little mucous membrane.

DR. SHURLY thought that in every case we should first form an idea of the nature of the tonsils and the amount to be removed. We may have bleeding from an abnormal distribution of arterial twigs. In using ignipuncture he does not put the point of the cautery directly into the crypts, but burns diagonally across them, including the lymph-spaces. He endeavors to substitute an acute inflammation for an old proliferative process. He differed decidedly from Dr. Seiler as to the direction of the greatest diameter of the tonsil.

DR. BOSWORTH, of New York, reported a case of

MELANCHOLIA CURED BY INTRANASAL OPERATION.

It occurred in a man, aged forty-two years, who suffered from depressive melancholia, at first periodic, but later constant, and became unfitted for business. He complained of the eyeballs feeling as if too large for the sockets, and of a bursting pain between the eyes. He had at different times been operated on for varicocele, stricture, ligation of the pudic artery, removal of the testicles, and hemorrhoids. He had worn glasses, had his eye-muscles cut, and one eye enucleated. He had been circumcised, had his spine cauterized, and worn a seton in his neck. Examination of the nose showed the right nostril nearly occluded by a thickened bulging of the cartilaginous septum and the left middle turbinate thickened, with myxomatous degeneration, and evidences of ethmoid disease. The nostrils were freed with saw and snare, and all symptoms quickly disappeared. The man has since remained perfectly well.

DR. BOSWORTH also reported

A CASE OF SUPPURATIVE ETHMOID DISEASE, FOLLOWED BY INVASION OF THE SPHENOIDAL SINUS, ABSCESS OF THE BRAIN, AND DEATH.

A dentist, aged thirty-three years, suffered from an offensive discharge from the left nostril, and later from the right, with severe headache and neuralgia of the left side of the head, without fever. Pus flowed down between the left middle turbinate and the septum. A diagnosis of old ethmoid disease with probably recent involvement of the sphenoid sinus was made. Free drainage was established with a sharp gouge, and for six days marked improvement of all symptoms was noted. Later they grew worse, and with a three-sixteenth-inch burr an attempt was made to penetrate the sphenoid, though it was not possible to say whether or not the sinus was actually entered. On the following day a chill occurred, with a temperature of 106°, the development of semicoma, and paralysis of the left arm and face. A second rigor occurred, and was followed by death. No autopsy was held, but it was thought that death was due to a brain-abscess. The lesson of this case was that, while ethmoid disease is not directly dangerous as a rule, it may become so indirectly. Dr. Bosworth believes that most of the so-called sphenoid disease is really ethmoid. He has seen one-hundred-and-fifty cases of the latter, but only two of the former, and both were fatal.

DR. J. H. BRYAN, of Washington, presented

A FURTHER CONTRIBUTION TO THE STUDY OF SUPPURATIVE DISEASE OF THE ACCESSORY SINUS.

He reported cases of abscess of the right maxillary sinus resulting from dental caries; suppurative ethmoiditis terminating in caries of the anterior ethmoidal cells; abscess of the left frontal sinus resulting from nasal polypi and hypertrophic rhinitis; and abscess of the frontal, ethmoidal, and maxillary sinuses, with caries of the fronto-ethmoidal cells. The last was especially interesting, inasmuch as a communication existed between the frontal sinus and the antrum. It was uncertain whether this was the result of disease or an anatomic anomaly. The condition has been found a few times in the dissecting-room.

DR. WRIGHT related the history of a case of antrum-disease in which it was impossible to discover the origin of the pus. He would condemn too early operation in this class of cases.

DR. INGALS thought the best way to open the sphenoid sinus was from below rather than anteriorly. This it was possible to do with an instrument used by dentists, in which the revolving drill worked at right-angles to the shaft of the instrument.

DR. GLEITSMANN preferred to open the sinus with a Schaeffer's probe passed four-and-one-half inches upward along the side of the middle turbinate, about one-eighth of an inch below its lower border.

DR. SHURLY had seen many cases of nasal discharge which he had thought due to neuritis, secondary to organic disease of the brain, which had affected the olfactory bulbs.

DR. DALY thought it preferable to slit up one side of the nose and lay it over on the face. In this way we could reach the sphenoid sinus more easily and much more safely.

DR. MULHALL thought that the brain was better protected from injury in the sphenoid region than in the ethmoid. Sphenoid disease apart from ethmoid he believed to be rare.

DR. THRASHER related a case somewhat similar to Dr. Bosworth's case of melancholia relieved by intranasal operation.

DR. W. K. SIMPSON, of New York, read a paper entitled

A CONSIDERATION OF SOME OF THE MORE IMPORTANT PRINCIPLES OF INTRANASAL SURGERY.

He said that the more accurately we could apply surgical principles to the treatment of nasal disease the greater would be our success. Conservative surgery might be defined as "knowing when not to interfere." We make mistakes occasionally, but they should serve as landmarks to guard against further error. He spoke particularly of the treatment of obstructive and hypertrophic rhinitis. The nose has a natural protective influence, and there is a pre-surgical or pre-operative period, during which we should do all we can by diet, clothing, habits, and a regulation of the general environment. In cases with a tendency to atrophy we should be very cautious about operating, and if we did operate we should endeavor to leave perfect symmetry and a smooth surface, with as little destruction of tissue as possible, and the least possible shock, hemorrhage, and danger of septic infection. The operation-wound should be treated as antiseptically as possible. Nasal surgeons are prone to be careless in minor details. Especial care should be taken to keep the left thumb and forefinger clean, as with these we wrap the cotton that goes on the applicator into the nose. Much of the "grippe," "severe cold," etc., after operation is nothing but mild sepsis.

DR. MULHALL believed that if we would use the cautery at a white heat and never allow it to cool *in situ* we would have no bad after-effects. He used a saturated solution of sodium bicarbonate to neutralize the effects of the radiated heat on the nasal mucosa.

DR. JAMES E. NEWCOMB, of New York, read a paper on

LUDWIG'S ANGINA,

which is generally defined by modern writers as a diffuse phlegmonous inflammation of the floor of the mouth and of the intermuscular and subcutaneous cellular tissue of the submaxillary region. The specific identity of the affection has always been a disputed point. Ludwig gave as its characteristic features: 1. A peculiar wooden induration of the tissues which does not receive impressions. 2. A uniform spread of this induration in such a way that it is always sharply bordered by a zone of entirely unaffected cellular tissue. 3. A hard, sublingual swelling, with a bolster-like mass around the interior of the lower jaw, of a deep-red or a bluish-red color.

It is impossible to harmonize the various conflicting statements, but it seems fair to regard the disease as an intensely infectious phlegmon, occurring under peculiar anatomic conditions. No pathognomonic germ has ever been discovered, only the ordinary bacteria of suppuration. Fatal cases show a general tissue-disorganization, with sloughs, ichor, or offensive pus.

Predisposing causes favoring the entrance of infection are dental eruption and caries, tonsillitis, disease of the buccal glands, and labial herpes. Cold, so frequently invoked as an exciting cause, is often but an undeterminable infection.

In the true Ludwig's disease the pus originates in a pyramidal space, the apex of which, situated below, corresponds to the point where the mylo hyoid muscle borders the genio-glossus, and the base of which, situated above, stretches along under the tongue. The internal face of the inferior maxilla and the mylo-hyoid muscle form its external (oblique) wall, and the genio-glossus and mylo-glossus its internal (vertical) wall. The germs first invading the sublingual may also penetrate the submaxillary sheath, or the latter may be attacked by the sublingual pus which has disassociated the fibers of the mylo-hyoid muscle.

The local and general symptoms are those of pus-formation, with subsequent pressure on surrounding parts. Special stress is laid upon the appearance at the inner aspect of the dental arcade of a pad or button-like area of induration. A differential diagnosis must be made from simple submaxillary adeno-phlegmon, osteomyelitis of the jaw, and Fleischmann's hygroma.

Statistics of 58 cases are sufficiently accurate for analysis. Of these 44 occurred in males, 9 in females, and 5 in infants whose sex was not stated. The maximum age was sixty-six years, and the minimum three months; 40 per cent. occurred between the ages of twenty and thirty years. Recovery is noted in 33 and death in 25. Bacteriologic findings in 9 instances were: Cocci of erysipelas, 2; streptococcus pyogenes, 4; staphylococcus pyogenes aureus, 1; and albus, 1. In one instance there was found a bacillus a little longer and narrower that the B. coli communis, but distinguishable from the latter by culture-reactions.

Treatment may be summed up as early incision, subsequent rigid antisepsis, and general support.

Very recently Semon has advanced the proposition that this malady and acute edema of the larynx, edematous laryngitis, phlegmonous pharyngitis, and pharyngeal erysipelas are all but different varieties of septic inflammation of the throat, differing only in localization and grade of severity, but all having the same general etiology. He maintains that this view constitutes a simple clinical application of bacteriologic principles to this group of septic inflammations.

DR. H. P. SWAIN, of New Haven, thought that some cases of peritonsillar suppuration of the lingual tonsil gave a symptom-group very much like that described.

A discussion on

TUBERCULOSIS OF THE UPPER AIR PASSAGES

was opened by DR. JONATHAN WRIGHT, of Brooklyn, who spoke of the etiology. Recent advances in bacteriologic knowledge have led us to modify greatly the postulates of Koch. We now know that bacteria can penetrate epithelial surfaces. Some of them are destroyed by phagocytosis and others by the fibroid induration that they themselves excite. It is believed that tuberculous infection can take place through the adenoid tissue at the base of the tongue, but it is conjectural whether the bacilli are actually found in the tissue itself or in the papillæ.

Much of our experimentation on animals is not in exact accord with the actual problems of clinical medicine, and we cannot reason directly from the results that follow the injection of tuberculous material into the bodies of animals by means of the syringe. All of us receive some tubercle-bacilli. Autopsies show evidences of arrested tuberculosis in one out of every two or three

bodies examined. The fatality is due not so much to the bacillus as to the bad general environment in which people live. Physicians come in contact with the bacillus daily, and yet the death-rate among them from pulmonary tuberculosis is not high. The bacillus alone is not enough to cause the disease.

As to laryngeal infection, the old corrosive-sputa theory of Louis has been abandoned. As to its frequency we are somewhat uncertain, for in pulmonary tuberculosis the larynx is often not examined; thus many lesions escape observation, and in many tuberculous ulcers are seen only when the patient is *in extremis*. Pyogenic cocci first make a breach in the epithelium, and then the bacillus enters. The bacillus itself cannot cause an abscess. Infection through glandular epithelium is a matter of dispute. There seems to be a wavy arrangement of the epithelium in the larynx that allows of its stretching during vocal effort, so that its protective influence is continuous. Lesions of the pharynx generally occur late in the disease or with acute miliary tuberculosis; nasal lesions generally at the end of pulmonary disease.

DR. C. C. RICE, of New York, presented a paper on

DIAGNOSIS.

Nasal Tuberculosis. Willigk found only one instance among 476 autopsies. It may occur either as an ulceration of the septum and floor of the nose, or as small papillary outgrowths, generally from the turbinates. It is doubtless frequently overlooked or it may coexist with specific septal disease. Nasal ulceration, with concomitant lung-disease, not yielding to potassium iodid, should awaken suspicion.

Tuberculosis of the Pharynx and Larynx. One case of the former and 237 of the latter were found in Willigk's series of 1307. Dr. Rice believed that faucial tuberculosis was associated more generally with acute miliary tuberculosis than with the usual chronic disease of the lungs. It may appear in the soft palate before it undergoes ulceration, but probably all parts of the system are invaded at the same time.

Tuberculosis of the Larynx. Eighty per cent. of all cases can be easily recognized. Of the remainder perhaps one-half require the microscope and administration of potassium iodid to determine definitely their nature. Unusually we have the typical semi-edematous, semi-inflamed conditions of the tuberculous infiltrations and the surface-ulceration, with its "moth-eaten" look. Such lesions are generally symmetrical and are situated upon an anemic base.

In incipient tuberculosis we find localized anemias of the hard and soft palate in throats otherwise healthy, and this with enlarged capillaries converging from the different portions of the palate toward the uvula. In addition we have elevation of the papillary layer in the inter-arytenoid commissure and feeble action of the internal laryngeal abductors. Dr. Rice regards recurring papilloma of the vocal bands as a suspicious circumstance, pointing toward tuberculosis. Arytenoid congestion or the slightest appearance of bogginess should also put us on our guard.

Then, finally, are the irregular cases with the frequent coexistence of syphilis and tubercle, or syphilis in the larynx and tubercle in the lungs. Rarely do we have with tubercle what is common enough with specific disease—adhesive inflammation between the anterior portions of the vocal bands. We may also have: 1. Granular hyperplasias or ordinary granulation-tissue. 2. The frequently seen inter-arytenoid water-like excrescences closely allied to papilloma of the larynx. 3. Small rounded tuberculoma beneath the mucosa, found to consist of true tubercle-tissue usually containing bacilli.

DR. SHURLY spoke of the

MEDICINAL TREATMENT.

He doubted whether much of the alleged post-mortem evidence of tuberculosis was entitled to credence. We may have "phthisis" without tuberculosis. The treatment is either local or general. Locally iodoform has given the speaker the best results. He uses ice freely. Climate and rest of voice were insisted upon. To modify pharyngeal and laryngeal ulceration chlorin gas, sodium formate, and iodoform are the most serviceable. As a specific plan iodin with gold and sodium chlorid has given good results; also oil of cloves and oil of castor. Gavage will enable the system to withstand the ravages of the disease and will also lower the temperature. We should never give meat-extracts alone, but always combined with vegetable foods in the form of gruel, which can be passed through a tube (sago, tapioca, etc.). Alcohol is generally too irritative for cases of laryngeal tuberculosis. Locally a mixture of eucalyptus, morphin, and cocain will greatly relieve pain. Tracheotomy is useless. So also in his hands were scarifying and curetting.

DR. J. W. GLEITSMANN, of New York, considered the

SURGICAL TREATMENT.

He considered curettement with the single or double instrument. Surgical treatment is, broadly speaking, either endo-laryngeal or extra-laryngeal. The former includes incision with knife or scissors, curettement, submucous injection, electrolysis, or the galvano-cautery; the latter, laryngotomy, with excision of diseased parts, extirpation of the larynx, and tracheotomy.

Dr. Gleitsmann has found on record eight total and seven partial extirpations of the larynx for tuberculous disease. In four of the cases of total laryngectomy the diagnosis was made before operation; in two the operation was performed on account of lupus and two had been considered carcinomatous; of the cases of partial laryngectomy, the operation was performed in five for tuberculosis, in one for lupus, and in one for supposed carcinoma.

Only six out of some seventy authors consulted speak disparagingly of curettement. It cannot, of course, exert a favorable influence on concomitant lung-disease, but we are justified in calling a case cured when, even if the lung-process continue, the laryngeal symptoms subside, the larynx looks normal, and no trace of the disease is found post mortem.

Contraindications are advanced lung-disease and hectic, disseminated laryngeal tuberculosis, leaving little or no area of healthy tissue, and extensive infiltration producing stenosis. Under the latter conditions tracheotomy is indicated. The claim made that curettement hastens the pulmonary disease is not supported. Hemorrhage, which, in any considerable amount is rare, can be checked by a mixture of lactic acid and ferric-

chlorid solution. Pain is avoided by the repeated use of strong solutions of cocain.

Curettement is analogous to the excision of a tuberculous joint. It removes a focus of infection which is a constant drain on a weakened system, and is in properly selected cases the best procedure at our command. The double curet will often remove at one setting the arytenoid infiltration, which is the great cause of dyspnea. Such procedure also lessens pain, through its removal of the abundant nerve-proliferation. The indications are as follows:

1. Primary tuberculous disease without lung-complication.

2. Cases with concomitant lung-disease, either incipient or which has stopped short of softening or hectic.

3. Especially circumscribed ulcerations and infiltrations.

4. Dense, hard swelling of the arytenoid region, ventricular band, posterior wall, tuberculous tumors, and affections of the epiglottis.

5. In advanced lung-disease with distressing dysphagia from arytenoid infiltration.

Heryng's single curets are best suited for cleaning and scraping ulcerations, and Krause's double curets and Heryng's rotary curets for excision of tuberculous infiltrations. Subglottic lesions can be operated upon with Scheinmann's forceps, and with laterally bent forceps an attempt may be made to reach the ventricles. Post-operative quiet is absolutely necessary. Lactic acid or pyoktanin, 1 or 2 per cent., should be applied daily until cicatrization is complete. The latter process occurs in from one to five weeks. Well-defined ulcerations do better than shallow and extensive ones; dense infiltrations, which are generally localized, better than edematous conditions.

Dr. Gleitsmann's own cases numbered twelve, all with lung-complications. Two operations were for infiltration of the posterior wall alone; one for such infiltration with affection of the ventricular band combined; four arytenoidectomies; three arytenoidectomies, and excision of the ventricular band; and two of the latter alone. Arytenoidectomy had to be performed twice on each of the ten patients on account of recurring infiltration. One patient died from heart-failure, and another from advanced lung-disease. Four are without recurrence of laryngeal disease from six to ten months. One of these had an affection of the posterior wall, another of the ventricular band, and two of the arytenoid region.

(To be concluded.)

NEWS ITEMS.

The Examinations of the Illinois State Board of Health.—The following preamble and resolution were unanimously adopted by the Illinois State Board of Health at a meeting held at Chicago on June 25, 1895:

Whereas, The faculty of the Northwestern University Woman's Medical College adopted a set of resolutions criticising the Illinois State Board of Health for having issued to three non-graduate students of said college the State certificate entitling them to practise medicine, whom they claim were not entitled to receive them, and charging the Board with having adopted a lax policy in numerous other instances, thereby seriously detracting from the usefulness of the Board; and

Whereas, Although the resolutions were "ordered to be placed before the Illinois State Board of Health," they were furnished to the various medical publications of the country simultaneously with their presentation to the Board, and before the Board had opportunity to make any defence; and

Whereas, The said college has not made any investigation of the methods or policy of the Board, and could not be in possession of information upon which to found such serious charges; and

Whereas, The secretary of the faculty admitted to the secretary of the Board that the resolutions were adopted without due consideration, and were not so applicable to the present Board; and

Whereas, In the past two years no certificate has been granted to any applicant upon an average rating of less than 80 per cent. on all branches, and the questions and examination papers and a tabulated record of all examinations are preserved, and are matters of record in the office; and

Whereas, It is not in the province of the Board to adopt any policy regarding the admission to its examinations of non-graduates, the law prescribing that "non-graduates shall submit themselves for examinations," and further prescribing that "the examinations shall be of an elementary and practical character." Therefore, be it

Resolved, That justice demands that the faculty of the Northwestern University Woman's Medical College, and all others interested, inform themselves as to the methods and policy of the Illinois State Board of Health in conducting its examinations, with a view to the establishment of the charges made, or of making such withdrawal, alteration, or explanation of the charges as the facts may warrant; and, further, that the faculty inquire as to whether any individual interest or personal animosity prompted the drafting and circulating of the resolutions.

(Signed) B. M. GRIFFITH, M.D.,
SARAH HACKETT STEVENSON, M.D.

For the Prevention of Blindness.—The following is the text of the legislation recently enacted in the State of Pennsylvania and approved by the Governor:

SECTION 1. Be it enacted by the Senate and House of Representatives of the Commonwealth of Pennsylvania in General Assembly met, and it is hereby enacted by the authority of the same, that should one or both eyes of an infant become inflamed or swollen or reddened at any time within two weeks after birth it shall be the duty of the midwife or nurse or other person having the care of such infant to report in writing within six hours after the discovery thereof to the health-officer or legally qualified practitioner of the city, town, or district in which the mother of the child resides the fact that such inflammation or swelling or redness exists.

SECTION 2. That it shall be the duty of said health-officer immediately upon receipt of said written report to notify the parents or the person having charge of said infant of the danger to the eye or eyes of said infant by reason of said condition from neglect of proper treatment of the same; and he shall also enclose to them directions for the proper treatment thereof.

SECTION 3. Every health officer shall furnish a copy

of this act to each person who is known to him to act as midwife or nurse in the city or town for which such health-officer is appointed, and the Secretary of State shall cause a sufficient number of copies of this act to be printed and supply the same to such health-officers on application.

SECTION 4. Any failure to comply with the provisions of this act shall be punishable by fine, not to exceed two-hundred dollars, or imprisonment, not to exceed thirty days, or both.

Doctor of State Medicine.—Rush Medical College of Chicago offers a degree in State medicine to graduates of not less than one year's standing who shall pass a rigid examination, including State medicine and hygiene, chemistry, physics and meteorology, engineering, morbid anatomy, vital statistics, medical jurisprudence, and law, after having completed six months' practical instruction in a laboratory approved by the faculty, and studied practically out-door sanitary work for four months under an approved officer of health.

The Medical Profession in Belgium.—The total number of qualified practitioners in Belgium is 2950. Of these, 884 dispense their own medicine. The proportion of doctors to population is 1 in 2122. The number of practitioners in Brussels is 558, being in the proportion of 1 to 1370 inhabitants. The proportion at Liége is 1 to 1771; at Ghent, 1 to 2186; and at Antwerp, 1 to 2251. There are in Belgium 2372 midwives, or 1 to every 2640 of population.—*British Medical Journal.*

A Medical School for Women in Russia is to be established at St. Petersburg, with means supplied from private resources. The curriculum is to correspond with that adopted by other foreign universities, and is to extend over a period of five years. Women under the age of twenty-one can only matriculate on the written permission of parents or guardians; married women on that of their husbands.

Professor Thomas H. Huxley, the distinguished scientist, died June 29th at Eastbourne, England, at the age of seventy years. He contributed liberally to a wide range of scientific subjects, and was an ardent disciple of Darwinian principles. Among his works are "Lectures on Comparative Anatomy" and "Lectures in Elementary Physiology."

Honors to Dr. Roswell Park and Dr. George Dock.—The degree of A.M. *honoris causa* has been conferred by Harvard College upon Dr. Roswell Park, of Buffalo, and Dr. George Dock, of Ann Arbor.

State Board of Medical Examiners of New Jersey.—At the June examinations of this Board over 40 per cent. (11 out of 26) of the candidates examined for licence to practise medicine in this State were rejected.

Professor Ewald Hering, of the University of Prague, has been made Professor of Physiology in the University of Leipsic as the successor to the late Carl Ludwig.

Dr. Luther F. Halsey, a prominent physician of Swedesboro, N. J., died suddenly on July 7th of angina pectoris, at the age of sixty-three years.

For the Report of the Trial of Amick vs. Reeves we have received from Dr. G. R. Fowler, $1.00; Dr. B. F. Miller, $1.00; Dr. Edmond Souchon, $5.00; Dr. George E. Jones, $2.00.

Dr. Ernest Laplace, of Philadelphia, has had the degree of LL.D. conferred on him by Georgetown University, of Washington, D. C.

Professor Mikulicz has been designated the successor of Trendelenburg in the Chair of Surgery in the University of Bonn.

Dr. Frederick T. Roberts has been appointed Professor of Medicine in University College, London.

Dr. Edward R. Palmer, of Louisville, lost his life in a bicycle collision on July 5th.

ACUTE PLASTIC IRITIS.

A Self-limited Disease.[1]

BY HENRY DICKSON BRUNS, M D.,

PROFESSOR OF DISEASES OF THE EYE IN THE NEW ORLEANS POLYCLINIC; SURGEON IN CHARGE OF THE EYE DEPARTMENT OF THE EYE, EAR, NOSE, AND THROAT HOSPITAL; LATE PATHOLOGIST TO THE CHARITY HOSPITAL, NEW ORLEANS.

IRITIS.

Definition: An inflammation of the anterior, variously colored portion of the uvea or middle coat of the eyeball. This middle coat, depending from the ciliary body posterior to the cornea, is visible through it, and is separated from it by the aqueous humor. It lies in front of and in contact with the crystalline lens under all conditions save that of extreme dilatation of the pupil.

Varieties: Serous, plastic, and purulent iritis. Serous iritis is, I believe, never a primary disease, but is always secondary and indicative of a choroidal affection. Any iritis may become purulent if the grade of inflammation rise sufficiently high. This is probable after a septic wound of the cornea, the iris, or the ciliary body. So an iritis may become subacute or chronic as the inflammation dies off, but not entirely out. It most often happens when some complication arising during the course of the disease prevents the restoration of the inflamed iris to a condition anatomically and functionally normal. Plastic iritis is characterized by the escape of plasma and white blood-corpuscles (lymph) from the engorged bloodvessels; this exudate, coagulating, obscures and clogs the tissue of the iris and glues it to the anterior face of the lens.

ACUTE PLASTIC IRITIS.

Acute plastic iritis is, therefore, the common and typical disease.

Cause: The predisposing causes are race, sex, and age. The negro is especially liable to iritis, as he is to all diseases of the uvea, either by reason of the saturation of the race with syphilis or from the embryologic relation between the uvea and his highly developed and functionally very active skin. Out of 173 unselected cases of acute, plastic, non-traumatic iritis recorded at my clinic in the Eye, Ear, Nose, and Throat Hospital, during the past two years, 73, or rather more than 42 per cent. were negroes, while people of African blood formed only 27 per cent. of the 4500 or more in attendance during the same period of time.

Men are more liable than women. Out of the total 173 cases 123 were males and 50 females—only 28 per cent., yet females form rather more than 50 per cent. of the total attendance at my clinic.

Out of 262 unselected cases the youngest was ten, the oldest seventy-one years old. The average age was thirty. I have taken the average of so many groups of cases that I feel perfectly safe in asserting the correctness of this figure.

Syphilis is by far the commonest exciting cause of the disease. Of 262 cases 115, more than 43 per cent., were undoubtedly of syphilitic origin; but the percentage, were it possible to determine it with certainty, is probably much greater. Rheumatism and gout are reckoned as causes next in frequency, yet only four out of 262 cases could with certainty be traced to this source. Rheumatic cases are certainly more common than this in private practice, and I suspect that most of these cases among the lower classes find their way into the general hospitals. Exposure to cold and dampness, especially local exposure, as, sitting by an open window duirng a railroad journey in inclement weather, can, and does, undoubtedly, excite a limited number of cases; but I doubt if this ever happens in a truly healthy person. Extension from adjacent structures, malaria, variola, scrofula, and tuberculosis are also causes cited.

Prognosis: The average duration of iritis, properly treated, is thirty days. Individual cases may recover in a week, or drag on for four or five months. This depends chiefly upon the presence or absence of complications, and this in turn hinges upon the severity of the initial attack and the promptness with which appropriate treatment is instituted.

Description: The degree of inflammation may vary from mildness to extreme severity. All the visible portion of the eyeball except the cornea, "the white of the eye," is injected, the injection being of a crude, raw-meat, red color, most marked immediately around the cornea. The cornea itself is usually very faintly hazy. This haziness, together with the presence of the exudate on and in the iris, gives it a dull, thick look, and in the

[1] Read before the Mississippi Medical Society at its annual meeting, April 11, 1895, at Jackson, Miss.

case of light-colored eyes causes a marked difference in hue between the inflamed and the unaffected organ. A blue or gray iris looks greenish; a hazel one becomes a darker reddish-brown. The pupil (*sphincter iridis*) is contracted, or at any rate never larger than that of the healthy eye. Its movements are sluggish, or it is absolutely fixed. This is due not only to the congestion and to the presence of products of inflammation, but to the actual gumming down of the iris to the lens by the exuded lymph. To decide this point the patient is seated facing a window, and one eye covered with a rolled-up handkerchief pressed upon it with the flat of the hand, while the other eye is alternately exposed to or shaded from the light by the hands of the surgeon. Pain is a marked symptom, though in rare instances it is slight, or even conspicuous by its absence. In character the pain is neuralgic, aching, or gnawing, and comes in paroxysms or outbursts, with more or less lengthy intervals of freedom and rest. Following the course of the fifth nerve, it radiates over the forehead and temple, around the orbit, down the side of the nose, or causes the whole side of the head to throb with intolerable anguish. The whole eyeball may ache or feel sore, and it is, as a rule, tender to touch. The pain is usually much worse at night. There is usually a little flinching from light (photophobia), and sight is nearly always bedimmed (acuity of vision diminished).

Complications: Owing to the gumming down of certain points of the pupillary margin to the lens, while the intermediate portions remain free to dilate, the pupil may have an irregular shape. This becomes much more conspicuous after the use of a mydriatic. These points of attachment of the iris to the lens (*posterior synechiæ*) are almost certain to occur if the pupil is not well dilated at the beginning of an attack. If the entire circumference of the pupil is sealed to the lens, we have circular posterior synechiæ and exclusion of the pupil, a condition which seriously interferes with the proper nutrition of the eyeball. Anterior synechiæ are due to penetrating wounds or ulcers of the cornea, giving escape to the aqueous humor, which carries the iris with it into the corneal wound, where it remains entangled. Corneal wounds are, of course, very common in traumatic iritis, while all severe corneal affections are likely to bring about secondary iritis. White or yellowish white exudate (lymph) from the iris may occupy more or less of the pupillary area (occlusion of the pupil), and the presence of such false membranes, together with posterior synechiæ, enables us to declare with certainty that iritis once existed. Blood sometimes escapes from the engorged vessels of the iris, and pus may be formed. The former is of course most common in traumatic iritis; the latter, in infected wounds of the tissue, in cases complicated with severe corneal ulcers and when gummata of the iris are breaking down. The fluids collect at the bottom of the anterior chamber, are more or less disturbed by movements of the head, and are known respectively as hypohema (hyphema) and hypopyon.

Diagnosis: There are only three conditions with which an acute iritis might be confounded: acute conjunctivitis, inflammatory glaucoma, and an acute corneal affection. The best method of defining and emphasizing the items of a differential diagnosis is by means of the "deadly parallel," so effectively employed by DaCosta in his now classic *Medical Diagnosis*. I have, therefore, drawn up the following scheme:

Acute Iritis.	*Acute Conjunctivitis.*
The injection is red, most marked near the cornea, much less toward the conjunctival culs-de-sac.	The injection is red, but is much less marked near the cornea and most toward and in the conjunctival culs-de-sac.
The vessels run deeply and straight toward the corneal margin (ciliary region).	The vessels are superficial, tortuous, and irregular in distribution.
Conjunctiva not much thickened, and distribution of vessels on everted lids clearly seen; it is not readily thrown into folds by working the lower lid over the ball with the finger.	The conjunctiva is thickened, especially on the everted lids, where the distribution of vessels is concealed in the general redness; it is easily thrown into folds.
There is no considerable hypersecretion of mucus.	There is hypersecretion of mucus; it is seen in flakes on the cornea or rolled in the conjunctival culs-de-sac, and dried on the eyelashes; the eyes are glued together by it in the morning.
Pain is neuralgic and paroxysmal; usually severe and worse at night; eyeball is tender and slight photophobia.	Pain is not severe; the eyeballs smart, burn, and feel "sandy" and dry all the time; there is no tenderness and no photophobia if the cornea is unaffected.
The iris is thick and dull-looking, and, if light, is discolored.	The iris appears normal.
The pupil is small, sluggish, or fixed; irregular, not round.	The pupil is normal. The cornea is clear if not secondarily affected; vision is normal.

Keratitis.
The injection is rose-pink; the vessels run straight and break into a fine network in the immediate vicinity of the cornea, where alone injection is conspicuous. The bulbar and palpebral conjunctivæ are not thick, and there is no hypersecretion.
Pain is moderate and pretty constant, sticking or lancinating; the eyeball is not tender; photophobia is severe and conspicuous; there is free lacrymation usually. The iris and pupil are normal, but sight of them is obscured in whole or in part by turbidity, opacities, scratches, roughnesses, foreign bodies, wounds or ulcers of cornea.

Acute Iritis.	*Keratitis.*
The cornea is clear unless there is a corneal ulcer or some other corneal complication.	The depth of the anterior chamber is normal. Sight is usually impaired by more or less corneal turbidity or opacity.
	Acute Glaucoma.
	The injection is red and the vessels distributed much as in iritis; the conjunctiva is not thickened: nor is there hypersecretion. The pain is of the same character as in iritis, but more severe; is not markedly worse at night.
The eyeball does not feel hard to the touch.	The eyeball is tender and very *hard* to the touch; the iris is discolored if light; the pupil is more or less *dilated*, sluggish or fixed; not black, but usually sea-green.
The anterior chamber is of normal depth.	The anterior chamber is shallow; the iris and lens are pushed close to the cornea; the cornea is hazy, steamy, or ground-glass-looking (this may be very slight).
Corneal sensitiveness is not diminished.	Corneal sensitiveness is diminished (if touched with camel's-hair brush or a wisp of cotton).
Vision not suddenly impaired; never completely lost, though sometimes dimmed.	Sight has been suddenly lost, or greatly dimmed with onset of the attack.
Atropin soothes, eserin greatly aggravates the pain.	Atropin-solution greatly aggravates, eserin mitigates all symptoms.

Treatment: Local and constitutional.[1] Local treatment consists in the instillation of a strong solution of atropin sulphate, in hot bathing of the closed eye and adjacent parts, and in the application of leeches. The constitutional remedies employed will depend upon the cause of the disease. If rheumatism be the cause we prescribe, of course, salicylates, iodids, change of climate, a visit to Hot Springs, or whatever may be our favorite means of combatting the diathesis. If syphilis be to blame I prefer mercury in the form of calomel and Dover's powders, as this helps to relieve pain; but for a busy man who has to be much "in evidence," parvules and triturates are very convenient. I also give potassium iodid freely—not less than a dram a day—in plenty of water or milk. The Turkish bath is very useful in enabling the patient to take the drug without unpleasant effects. The usual common sense measures of regulating the bowels and avoiding undue exposure will, of course, be employed. Rest in bed for a day or two may be sometimes necessary, but as a rule the patient provided with dark glasses goes about as usual, and is probably the better for the out-of-door exercise and the distraction of his attention. It is to the vigorous and exact application of local measures, however, that attention should be persistently directed. The solution of atropin, our "sovereignest remedy," should not be weaker than one grain to the dram, and it should be instilled at least once an hour for the first twelve or thirty-six hours until the pupil is widely and smoothly dilated, and thereafter as frequently as may be necessary to maintain extreme dilatation. The first thirty-six waking hours are meant, for no one should awaken a patient with iritis from his all too broken sleep for any reason. If full dilatation is not obtained within this time it is rarely secured. When the instillation is made the patient should be lying down, or have the head thrown very far back, and the lids should be held apart for a minute or more to insure thorough application and absorption of the drug. The instillation of atropin should be followed by bathing the closed eye and neighboring parts with the very hottest water the skin can stand. Iritis is not a disease to be trifled with; the atropin-solution must be of full strength, it must be used promptly and effectively, and the water must be stinging hot, not warm, if the patient is to receive his eye from the hands of the surgeon, so to speak, anatomically and functionally restored. Few who are not especially experienced seem to realize the importance of this vigorous use of atropin in iritis and the sinister effect of permanent posterior synechiæ upon the future health and perfection of the organ. Once the pupil is fully and freely dilated, no matter how severe the suffering may have been, no matter how the case may have dragged along, when recovery does take place the disease is truly cured; but let permanent synechiæ be formed by too long delay, or by feebleness of attack on the part of the physician, and the weary road of relapse, of chronic inflammation, of plastic exudation, and pathologic cataract lies before the patient. When leeches are employed, three or four should be put on near the outer canthus, and the bleeding should be free. This and the other local measures markedly relieve the pain, for which purpose the inunction of a salve of one ounce of mercurial ointment to a dram of belladonna extract on the forehead is also very useful. Opiates are to be avoided if possible. It must be borne in mind, however, that this free use of atropin may bring about poisoning by the drug, an accident especially common in elderly persons, when opiates at once occupy the highest place of usefulness.

There can be but little doubt that constitutional treatment is very effective in removing the tendency to relapse in syphilic iritis, and we should be equally successful in rheumatic cases did we possess as certain means of exorcising the poison; but—and this is the most unorthodox portion of my paper—I am without evidence to show that the best and fullest constitutional treatment has the slightest effect in abridging the duration of iritis, while I have some

[1] All cases of "neuralgia" of one side of the head, accompanied by inflammation of the eye, must be regarded with extreme suspicion; they are usually cases of iritis or glaucoma.

facts to show, what I have long suspected, that acute, non-traumatic iritis is a self-limited disease. By this I mean that while we prevent permanent injury, squeeze the blood from the iris, insure rest, and soothe pain, by the use of atropin, and so render the course of the disease shorter than if, utterly neglected, it were allowed to run through all the tedious stages of plastic adhesion and chronic inflammation, we do not, so far as I know, by the addition of the best constitutional treatment shorten the course of a case that is being locally treated. We can in such matters speak, of course, only of averages. I have now complete notes of 105 unselected cases of acute, non-traumatic, plastic iritis. They were treated by myself and others until they were discharged as fully cured. In 1893 I published a preliminary note on 69 of these cases in the *Transactions* of the Louisiana State Medical Society. At that time I found the average duration of 46 cases treated by both local and constitutional measures to be $30\frac{9}{46}$ days, and the average duration of 23 cases treated by local measures alone to be $24\frac{5}{23}$ days.

The 105 cases were collected in two groups: One of 63 cases at the Charity Hospital, from 1883 to 1891, and one of 42 cases at the Eye, Ear, and Nose Hospital, during the years 1893–1894. In group No. 1, 19 cases treated locally had an average duration of 20 days, while 44 cases treated both locally and constitutionally had an average duration of 39 days. In group No. 2, 33 cases treated locally had an average duration of 27 days, while 9 cases treated both locally and constitutionally, had an average duration of 29 days. Combining the two groups so as to get larger and, therefore, fairer figures, we find that 52 cases treated by local measures alone had an average duration of 25 days; while 53 cases locally and constitutionally treated had an average of 34 days. Or, having some regard to causation, we find that of 44 non-specific cases those treated locally had an average duration of 23 days; those locally and constitutionally an average of 37 days; of 61 syphilitic cases those treated by local measures alone had an average duration of 27 days; those locally and constitutionally an average of 31 days. The accompanying table shows these figures at a glance, and also shows all the possible combinations by which these results might be varied, and yet there is no material variation, twist and turn them as we may.

Group No. 1, local treatment only, average 20 days + 27 days (average of Group No. 2) = 47 days; mean = 23 days.

Group No. 1, local and general treatment, average 39 days + 29 days (average of Group No. 2) = 68 days; mean 34 days.

All cases under local treatment only, 52 cases, average 25 days; all cases under local and general treatment, 53 cases, average 34 days: total, 105 cases.

All non-specific cases, 44; local treatment only, average 23 days, mean 25 days; local and general treatment, average 37 days, mean 34 days.

All specific cases, 61; local treatment only, average 27 days, mean 34 days: local and general treatment, average 31 days, mean 34 days.

It cannot be denied that a larger number of cases might lead to a different conclusion, but I do not think it probable, in face of the fact that the two groups collected at different times in distinct hospitals, and subject to the treatment of different surgeons, give practically identical results, and that the first obtained 69 cases analyzed in 1893 did not show essentially varying conclusions. The only fair deduction from this table is:

Non-traumatic, acute, plastic iritis runs an average course of thirty days' duration (twenty-five to thirty-five); variation in duration may be determined by the severity of the initial attack and by the length of time the disease is neglected, and (hence) by complications that arise (posterior synechiæ, etc.), but extreme dilatation of the pupil having been secured (by atropin and hot bathing), other treatment is powerless to abridge this average duration.

GOITER IN MICHIGAN.[1]

BY GEORGE DOCK, M.D.,
OF ANN ARBOR, MICH.,
PROFESSOR OF MEDICINE IN THE UNIVERSITY OF MICHIGAN.

VERY soon after beginning medical work in Michigan I had occasion to call attention in clinical demonstrations to the frequent occurrence of goiter, and within a few weeks I saw more cases than I had seen in several years, with more material, in either Philadelphia or Galveston. Visits to some of the most promising goitrous districts failed of realization for several years, but in the summer of 1894, through the kindness of Dr. E. H. Pomeroy and his associates on the medical staff of the Calumet and Hecla Mining Company, at Calumet, Michigan, I saw a large number of very interesting cases. Since then I have sent out question-blanks to a large number of physicians in all parts of the State. From the answers to these, and from my own observations on patients in my clinic, I have obtained the data on which the following remarks are based.

Records of goiter in the United States are curiously rare. Since the beginning of the century, following the monograph of Barton,[2] no general survey of the subject seems to have been made, and even accounts of local endemics are rare. I have limited my own investigations to Michigan, although I have found from observation and inquiry that parts of Ohio and Indiana, still more the States

[1] Read before the Association of American Physicians, May 31, 1895.

[2] A memoir concerning the disease goiter as it prevails in different parts of North America. Philadelphia, 1800.

(including parts of Canada) bordering on Lakes Michigan, Superior, and Huron, contain a good many cases. The prevalence of goiter in Canada has been mentioned by several writers. An important reference to the subject is contained in Dr. Osler's report on "Sporadic Cretinism in America."[1]

Goiter occurs in all parts of Michigan. It is most prevalent in the northern part (both peninsulas), but the southern part of the lower peninsula, especially the lower two tiers of counties from lake to lake, shows a large proportion. In Calumet, the physicians of the company kindly made a census and found fifty well-marked cases in a population of 14,000. At the Central Mine, a few miles away, my friend, Dr. John MacRae, found ten cases among less than 2000 people. In Adrian, in the southeastern part of the State, Dr. M. R. Morden reports thirty cases in a population of less than 9000. In Gaylord, Otsego County, Dr. N. I. Parmater writes that of all children born there, and reaching puberty, one-fourth have goiters. I have seen a number of cases from the counties directly adjacent to Otsego, but they are so sparsely settled that it is difficult to get definite information. I have not attempted to make a census of cases, as many of my correspondents do not give figures. Fifty-two reporters give a total of 477 cases, not including the cases in the copper-region. The extent of the disease, as shown by the figures, does not compare with that in the goitrous regions of Europe, but is, nevertheless, a matter of importance and interest.

In a large majority of cases the goiters affect natives of America, and usually also natives of the district. Immigrants of all nationalities, and many of these are represented in Michigan, are frequently affected. Among others, the French-Canadians must be mentioned. I made a special effort to discover the conditions as regards Indians, many of whom live in different parts of the State. Among the older writers there is a want of harmony concerning goiter in Indians. This may be due to a fact I have noticed, that the red man seems to repel scientific investigation. Most of the reporters living near Indians could say nothing about them. However, Dr. R. B. Armstrong reports goiter as common among the Indians near Charlevoix. Dr. J. Wells Church, of Drummond, Chippewa County, says they have it, but rarely. Dr. H. B. Hatch, of Hart, Oceana County, has seen a number of cases; and other cases have been observed by Drs. G. C. Hafford, of Nahma, Delta County; E. B. Patterson, of Michigamme, Marquette County; John W. Decker, of Lake City, Missaukee County; O. L. Ramsdell, of Petoskey; C. N. Sower, of Pentwater, Oceana County; and L. A. Harris, of Vanderbilt, Otsego County.

In Michigan, as elsewhere, goiter develops most frequently about puberty, next in early middle life. No age is exempt. No case has come under my observation in which the goiter was congenital, though I have known of several in very early childhood. Goiter frequently affects the parents, especially the mother, and also children. I have seen a family in which a mother and eight grown-up children had goiters.

As regards sex, females seem to predominate.

In most cases the goiters are comparatively small, not causing an increase of more than two or three inches in the circumference of the neck. Occasionally they are larger, and I am told of some "as large as a man's head," and of one that extends to the chin. I have never seen these myself, and even the largest native goiter I have seen would excite little interest in Savoy. Owing to this there is in most cases comparative symmetry in the growths, and I have seen but one case in which the tumor had a grotesque shape, so common in Switzerland. No histologic examinations have been made, but the tumors have all the physical characteristics of various forms of benign struma.

I have endeavored to learn of cases of cretinism, and, although I am told of one case, I have not seen it myself, and cannot vouch for the diagnosis. An interesting case coming under my own observation was that of an idiot girl, of eleven years, with a large goiter affecting the isthmus and both lobes. The goiter was of long standing. None of the physical peculiarities of cretinism was present.

No case of myxedema has come under my immediate notice. On the occasion of the report of a case before the Michigan State Medical Society in 1894, by Dr. J. A. Wessinger, I spoke of the extent of goiter in Michigan and the advisability of looking up cases of myxedema; but so far as I can learn no other case has been reported. It is well known that in certain places where goiter is endemic myxedema is rare or absent.

Exophthalmic goiter seems to be unusually prevalent in Michigan, but without any evident relation to simple goiter. I have not included the latter in this study.

Goiter affects the lower animals almost always where it is common in man. Horses seem most frequently affected, then dogs, calves, and lambs. Cows and sheep do not seem to have goiter as often as the others. In a short time, on one day, in Calumet, I saw six goitrous horses and heard of a number of others. Most of the goiters were small and unilateral, not as large as a man's fist, but I was told of larger ones. Dr. Morden, of Adrian, reports what was perhaps a cystic goiter in a squirrel.

[1] American Journal of the Medical Sciences, November, 1893, p. 503.

Of all the numerous factors supposed to be concerned in the production of goiter, the only one regarding the existence and importance of which there is now any probability is some unknown substance in drinking-water. That water is the cause of endemic goiter is one of the oldest and one of the most universal beliefs, but the peccant material has been differently conceived at different times.

All the older ideas, according to which goiter was thought to be due to lime, magnesia, or other mineral in the water, have gone the way of the glacial water theory and the "bronchin" of Vest, and now, in accordance with current knowledge, the pathogenic substance is supposed to be either a microbe or a toxin. Nothing definite, however, is yet known in this connection. The relations of goiter in Michigan are such as to make all other causes doubtful, even if they had not been disposed of before. Here are no glaciers, no deep valleys, no long-continued mists and fogs, no carrying of heavy loads on the head, no inter-marrying. The cases come from all classes of society, but even in the poorest the hygienic conditions are no worse than in many places where goiters are never seen. Many cases that I have seen have lived amid unusually favorable hygienic surroundings. As for the geologic formation, sometimes looked on as important, we find goiters here as well on the drift as on the Laurentian, and in many intermediate formations.

In the cases of goiter that I have seen in Michigan a very large proportion of the patients have used well-water, and almost without exception my correspondents state that the same is true of the cases they report. Near Ann Arbor, where goiter is not so common as in some other parts of the State, one of my patients, a girl of sixteen years, developed goiter a few months after a new well was put in use, and I was told that several others who used the water got goiters about the same time. In response to my inquiry as to change of water and its results, Dr. N. H. Taylor, of Ludington, writes that goiter has become much less frequent there since lake-water was substituted for well-water. An opportunity for observing the effect of change of water is now being given at Calumet. Formerly all drinking-water there was derived from wells, but recently an abundant supply has been obtained from Lake Superior, the inlet being in a place as free from contamination as possible. The result of this investigation must be awaited with great interest.

Although it is not within the scope of this paper to consider the clinical features of goiter, I wish to add what testimony I can to a diagnostic feature that does not seem to be generally appreciated. Guttmann[1] has called attention to the fact that in the goiter of Graves' disease there is an arterial murmur over the tumor, which is not the case in other forms of goiter. Kocher expresses himself in accord with this view. For nearly four years I have paid attention to this sign, and have not yet seen a case of simple goiter in which there was a murmur, even in the case of very rapidly growing tumors. I have once heard a systolic murmur over the goiter of a horse. The growth was very hard, and I think the murmur must have been due to pressure. It had a blowing character, different from that heard over the goiter of Graves' disease, regarding which I agree with Guttmann. In cases of Graves' disease from which exophthalmos is absent this sign can, therefore, I think, be used with advantage.

I do not intend to speak now of the medical treatment of goiter. The difference of opinion expressed on that subject by my correspondents is characteristic of a disease like goiter, which in some cases can be removed by the royal touch, and in others withstands everything but the knife. I have made some trials with dried thyroid, kindly furnished me by Messrs. Parke, Davis & Company and by the Armour Company. The cases treated are too few to allow me to draw any conclusions, but lead me toward those reached by Bruns, Kocher, and others, viz.: that in young persons the remedy is useful, and should be tried further. The following observation, made on a recent case, is so interesting that I give it now:

A man of sixty-six years came to my clinic with a goiter which he said had grown in six weeks. Both lobes and the isthmus were enlarged, forming a symmetrical tumor, increasing the size of the neck more than two inches. The most remarkable thing about the tumor was that it was extremely hard, evenly nodular, and grew downward, so that the lower end could not be freed from the sternum and clavicles, and the growth hardly moved at all with the movements of swallowing. There was neither thrill nor murmur over the growth. The upper rings of the trachea were pressed in by the growth to a considerable degree. Iodin, internally and locally, including ointment of mercuric iodid, had been used without influencing the size of the tumor. From the alleged rapidity of growth and other features I suspected malignant disease, and advised the patient to remain under observation for a few days. He was put on gram-doses of thyroid powder three times a day. After taking this for two days without unpleasant symptoms, the patient was obliged to go home on account of business. The thyroid powder was stopped. A week later the man wrote that the goiter had disappeared, that the neck measured 15½ inches, one-half inch more than normal, and that the symptoms of pressure on the trachea had disappeared.

The sudden disappearance of goiters in young persons, especially vascular goiters, is of course com-

[1] In his Lehrbuch, and in the Deutsche medicin. Wochenschrift, 1893, No. 11, p. 254.

mon. In this case, however, I think the medication must have had something to do with the change.

Although in most cases of goiter there are no symptoms and treatment is never asked for, in some unpleasant, dangerous, or fatal results occur, so that measures should be taken to check the disease, and the more important factors in prevention should be known.

In addition to improvement in the surroundings of the patient, when needed, there are two things to which attention may be drawn, sterilizing the drinking-water and removal of the patient to a non-goitrous district. The effect of change from well-water to lake-water, or river-water, should be more thoroughly tested. In the meantime all drinking-water in the goitrous districts should be boiled. For a long time I have advised goitrous patients to use boiled water, but, as they also used medical treatment, the effect cannot be determined. At the Congress of the Pyrenese Association in 1891 a memorial was addressed to the Minister of Instruction, in which the general use of filters was advocated. This may, no doubt, be of some additional value, but boiling alone can be practised more generally and more safely than the use of filters.

In my experience removal of a patient with a growing or intractable goiter to a part of the country where the disease is less common has been followed by complete disappearance of the tumor, and some of my correspondents have had similar experience.

I wish to express here my thanks for the useful information furnished by a large number of correspondents impossible of enumeration in the paper.

EXTIRPATION AND COLOTOMY IN CASES OF CARCINOMA OF THE RECTUM.[1]

BY LEWIS H. ADLER, JR., M.D.:
PROFESSOR OF DISEASES OF THE RECTUM, PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE; SURGEON TO THE CHARITY HOSPITAL AND TO THE OUT-PATIENT DEPARTMENT OF THE EPISCOPAL HOSPITAL, PHILADELPHIA.

COLOTOMY and extirpation are two recognized procedures for the relief of malignant disease of the rectum. Both operations offer the patient a chance of prolonging life; and, in addition, extirpation holds out the possibility, in selected cases, of effecting a radical cure.

The choice between these two methods is a question of uncertainty only in a relatively small group of cases. Extirpation is not to be considered in the majority of instances, for the reason that the disease is usually an incurable one, and, by virtue of its concealed position within the rectum, its presence is not revealed or even suspected until the growth has existed for some time. Furthermore, it is rare for carcinoma of the rectum in its incipiency to manifest itself by any symptom pointing to a lesion within the bowel. This is a familiar observation to all surgeons.

It frequently happens that a patient comes complaining of slight diarrhea or other mild rectal trouble, and an examination unexpectedly reveals the fact that carcinoma is present to such an extent that it is obvious that the neoplasm has existed for a considerable period. Consequently its complete removal is often rendered impossible. Again, the patient's vitality is such that so grave an operation as excision, requiring considerable time for its performance, is contra-indicated.

In arguing thus I would not convey an impression that I am opposed to extirpation for malignant disease of the rectum in suitable cases. On the contrary, I firmly believe it to be a perfectly justifiable operation when the growth is circumscribed and confined to the lower four or five inches of the bowel; provided, however, that the tumor does not involve all the coats of the intestine, that it has not attacked the viscera which are intimately associated with the anterior wall of the rectum, that it has not invaded the pelvic glands or, by metastasis, any of the other organs of the body, and, finally, that its growth be not rapid or have a tendency to spread widely. From these considerations it naturally follows that the number of patients who can be benefitted by excision of the disease is comparatively small.

Colotomy, on the other hand, is indicated in a large number of instances in which it is quite impracticable to attempt an excision. The advantages of the operation lie partly in the relief it affords to symptoms and partly as a means of retarding the growth of the neoplasm.

To indicate the relief afforded such patients by colotomy I cannot do better than quote the opinion of Kelsey on the subject, as expressed in the fourth edition of his work, *Diseases of the Rectum and Anus*.[1] This authority is not only a strong advocate of the operation, but is also in a position to judge of its merits by reason of his large experience. He thus states his views:

"As to the benefits arising from the operation too much can scarcely be said. That it prolongs life by the relief of pain, the preventing of obstruction, and retarding the growth of cancerous disease, is beyond question. That it substitutes in many cases a painless death for one of great agony is indisputable. The idea that it is as well to let a patient die as to subject him to a colotomy has no supporters among surgeons who have had any experience with these cases. Indeed, I think that the practitioner who to-day sat by and allowed a patient to die of obstruction because of any sentiment against this procedure would hardly be held blame-

[1] Read before the Surgical Section of the American Medical Association at Baltimore, Md., May, 1895.

[1] Pp. 409 and 410.

less. I can only say that, after trying every other means of treatment and being obliged to admit the fruitlessness of them all, I have come, with most others, to admit the great benefits of colotomy, and *have never performed it in any case in which either the patient or myself has afterward regretted it.*" (Italics mine.)

In another article Kelsey[1] mentions even more minutely the advantages of this operation, as follows:

"Colotomy, especially inguinal colotomy, relieves pain; does away with the constant tenesmus and discharge from the rectum, which, by their exhausting effects are the immediate cause of death; delays the development of the disease by preventing the straining and congestion of defecation; prevents absolutely the complication of intestinal obstruction, which is another cause of death; enables the patient to sleep, eat, and gain flesh, and often makes him think himself cured in spite of the plainest prognosis to the contrary. Instead of passing his days and nights upon the commode, wearing out his life in the effort to free the bowel from the irritation, he has one or, perhaps, two solid fecal evacuations from the groin in twenty-four hours."

In conclusion, I would allude to one more topic, to wit: The choice of sites of opening the colon. I mention this subject with the sole purpose of eliciting the present views of the members of this society. My own belief is that the inguinal region is to be preferred in the majority of cases. Its advantages over the lumbar operation are, to my mind:

1. The smaller incision and lesser depth of the wound requisite to reach the colon, and the minimum amount of disturbance of the structures overlying the seat of operation.

2. The greater facility offered for the exploration of the abdomen, when such a procedure is required.

3. The better position for safe anesthesia during the operation.

4. The comparative ease with which the colon may be identified in this position and the little difficulty experienced in fixing the bowel to the skin without undue tension on the stitches.

5. The greater readiness with which a good spur may be formed.

6. The convenience to the patient of the site, for purposes of cleanliness and for the adjustment of pads; and

7. Recent statistics seem to indicate that it is the less dangerous operation.

1610 ARCH STREET.

Dr. John Guiteras, at the request of the Surgeon of the Marine-Hospital Service, has gone to Tampa, Fla., to aid the government in formulating and effectuating rigid quarantine-regulations against yellow fever.

CLINICAL MEMORANDA.

AMYOTROPHIC LATERAL SCLEROSIS IN A MAN SIXTY-EIGHT YEARS OLD, SIMULATING AT FIRST PARALYSIS AGITANS.

BY WILLIAM C. KRAUSS, M.D.,
OF BUFFALO, N. Y.;
PROFESSOR OF NERVOUS DISEASES IN THE MEDICAL DEPARTMENT OF THE NIAGARA UNIVERSITY; NEUROLOGIST TO THE ERIE CO. HOSPITAL.

C. B., aged sixty-eight years; height, 5 feet 6½ inches; weight, 190 pounds; occupation, lawyer; was an ex-judge of the Superior Court of B. His father died at the age of sixty-two years; his mother is living at the age of eighty-eight years. His grandparents lived to old age. He passed through a severe attack of measles when five years old, and made a perfect recovery. Some years later he was stricken with pneumonia and recovered fully; otherwise his early youth and manhood were passed without any noteworthy occurrences. He graduated from the University of Michigan when twenty-three years old, taught school for several years, and then began the study of law. He was eminently successful in his profession, and was elected Judge of the Superior Court of B., later becoming its Chief Justice. He was highly respected by men of all parties, possessed a rare legal talent, good judgment, and an opinion that was much sought after by his fellow-townsmen. He was a hard worker and a careful student, the early morning hours greeting him many times before his bed. He lived well, though not sumptuously, never indulged in excesses, was a moderate drinker, an ordinary smoker, took considerable exercise, and paid reasonable attention to his physical health. For seven years he had been affected every autumn with articular rheumatism, involving the joints of the lower extremities, while those of the upper remained exempt. Sometimes a gouty tendency was present, though not frequently. For seventeen years there had developed a subconjunctival hemorrhage sometimes in the right eye, sometimes in the left eye These hemorrhages would be absorbed in the course of a week or ten days and would reappear the following fall.

During the summer of 1893 he was troubled with vague symptoms which he ascribed to influenza, but he paid little attention to them. While in Chicago, attending the Fair, he noticed that it was hard for him to step over the gutters, his limbs seemed so stiff and "loggy." He tired easily while walking about the grounds, could not ascend the steps, and had to take his time in going from building to building. This was the first he observed of any difficulty in locomotion, and as he had some rheumatic pains in his limbs he naturally thought it was the result of his rheumatism. On his return home he still experienced the same difficulty in walking, and was obliged to take a carriage in going to or coming from his office. This continued to grow worse, and on January 9, 1894, I was called in consultation.

Although I had seen the man on the streets and in the court-room several times previously, I nevertheless was struck by his changed appearance, and, at first sight, made a diagnosis of paralysis agitans without tremor. So sure was I of my diagnosis that I communicated the result of my examination to the family physician, who

informed me that he was also of the same opinion. The same diagnosis was made by a fellow-neurologist of Buffalo, and by another physician whose practice is a large and varied one.

Upon examination, I found a large and muscular man, with gray hair and whiskers, whose face wore the heavy masked expression so common to Parkinson's disease. The movement of the facial muscles was mechanical and measured, so that one could almost observe an interval of time between the volition or intention to move the muscles and their actual obedience to the will. His head was inclined forward, the shoulders were rounded and drooping, his hands lay motionless in his lap, but in the "bread-crumbling" or "holding-a-pencil" position, while his feet rested heavily on the floor. His speech was slow, solemn, deliberate, and in a monotone, very much unlike his natural delivery, which was rapid, forcible, and undulating. He complained of no pain, no disturbance of sensation, and "if I could walk better," he said, "I would be all right." His locomotion and station were identical with those of paralysis agitans, *i. e.*, the head and body were well inclined forward, the arms were held close to the body, the legs were stiffened and slightly flexed at the knees, and he moved them in a shuffling, obstinate manner, hardly taking the feet off the floor—resembling very much the gait of a surly, sulky child. Once started, it was difficult for him to stop unless he grasped something to support himself (propulsion).

Retropulsion was also present, but to a much less degree. The movements of the arms and head were slow, and accomplished as if trying to overcome some obstacle. There was nothing abnormal about sensation; the rectal and vesical reflexes were unimpaired; the organs of special sense functionated normally, except, of course, his speech. The tendon-reflexes and the muscular reflexes were neither exaggerated nor diminished; the muscular power was well preserved for a man of his age, and his mind was as clear and unobscured as in former days of activity and usefulness. The pulse ranged between 70 and 80; the temperature was never increased; the appetite was good, the bowels regular, and the urine normal; but his sleep was not the same restful sleep to which he had formerly been accustomed. Occasionally his attendants would notice a faint flush on his cheeks, and at night he would feel heated. I kept a careful watch over him in the hope of being able to discover the tremor as soon as it appeared, but instead of a tremor I observed other symptoms coming to the surface that seemed to shake my confidence in the former diagnosis. In the summer of 1894 the man began to complain of difficulty in breathing and of coughing, and his laughter was at times uncontrollable. Instead of the healthy inspiring laughter innate in a judge, it was a sickly puerile laughter without force or character. He was troubled greatly in swallowing, and had to eat very slowly and deliberately; sometimes in eating he would choke and have fits of coughing. His voice became husky, and the words were mumbling and hardly understandable to an outsider. His legs and arms were weakening rapidly, so that in the space of a few months he possessed hardly any control over them.

On December 1, 1894, an examination revealed the following condition:

The muscles about the shoulder, as the deltoid, trapezius, the rhomboids, major and minor, the arm-muscles, as the biceps, triceps, coraco-brachialis, the flexors, extensors, supinators, and pronators; and the hand-muscles, as the interossei, and the muscles of the thenar and hypothenar eminences, had undergone marked atrophy. The man could no longer raise the hands to his mouth, and the grip of the hands was *nil*. The shoulder-muscles were equally powerless. Contractures of the flexors of the fingers were present in the right hand, less in the left, and the right hand was beginning to assume the *main en griffe* appearance. Fibrillary contractions were present, more on the right than on the left side. The triceps and the biceps tendon-reflexes were greatly exaggerated, and likewise the muscular and periosteal reflexes. The masseter reflex could not be elicited. Sensation to touch, pain, heat, cold, and pressure was unaffected. Vasomotor disturbances were not present; the hands and feet were continually warm. The legs had become nearly powerless, and the man was unable to make much headway in walking, and none at all unless supported on both sides. The loss of power was not due to the wasting of the muscles, because, although considerable atrophy had taken place, the leg-muscles were still large and well preserved.

An electric examination of the muscles was not made. The patellar tendon-reflexes were greatly exaggerated; ankle-clonus was present, but only within the previous few weeks had it appeared. The rectal and vesical reflexes were unimpaired. Sensory disturbances were wanting.

An examination made on February 1, 1895, resulted as follows: The condition of the patient had grown steadily worse, and he now presented the typical picture of amyotrophic lateral sclerosis with implication of the medulla. The bulbar phenomena consisted in an unintelligible mumbling, with an occasional word or two clearly spoken, permitting the nurse to care for his wants. The labials and linguals could not be pronounced; the gutturals, however, could be pronounced quite distinctly, especially when the patient was not fatigued. The voice was hoarse, husky, and explosive. The movements of the tongue were restricted, the tip scarcely reaching the lips when protruded; it had also undergone some atrophy, although not to such an extent as I have occasionally seen in these cases. The lips, at first slightly swollen and compressible, were now weak and flabby, requiring some effort to keep them closed. During a paroxysm of coughing they flapped like the sails of a boat under an adverse wind. The peculiar appearance of the lower face, that of "unpleasant astonishment," caused by the drooping of the lower lip and deepening of the naso-labial folds, was well illustrated. The pharynx and larynx were in part affected, as manifested by the escape of fluids through the nostrils, foreign bodies, especially food entering the glottis, causing fits of coughing, etc. The disturbance of respiration was very pronounced, consisting of dyspnea and difficulty in coughing. Singultus had never been present. No paresis of the upper face-muscles or of the eye-muscles could be proved, nor disturbances of the motor or sensory branches of the trigeminus nerves. The atrophy of the muscles of the shoulder, arm, and hand was complete, rendering the upper extremities absolutely helpless. Fibrillary contractions were well marked in the affected muscles, and contractures implicating the elbow, the

wrist, and the hand-joints had made their appearence. The superficial and deep reflexes, likewise the tendon-reflexes, were greatly exaggerated. Sensory disturbances of all kinds were absent. The muscles of the lower extremities were less atrophied than those of the upper, but were equally powerless. The rectal and vesical reflexes were intact.

Urinary examination showed nothing abnormal; examination of the blood showed a great diminution in the quantity of hemoglobin. The heart's action was feeble, but regular and uniform. The greatest distress seemed to come from the respiratory organs; a bronchitis, having developed within the preceding week, occasioned great annoyance, provoking fits of coughing and consequent general prostration.

On the morning of February 26, 1895, the patient was able to sit in a chair for a short time, complaining of great dyspnea and difficulty of raising mucus, but was otherwise in his usual condition. At noon of the same day respiratory failure supervened, and death ensued without any great struggle.

An autopsy was not permitted.

The case is worthy of publication for several reasons, even if amyotrophic lateral sclerosis were a common instead of a very uncommon affection. In my hospital-practice and private practice I have seen but two such cases in Buffalo, in a period of five years; one in consultation with Dr. Pohl, occurring in a man thirty-eight years of age, who presented a typical picture of this disease, enabling a positive diagnosis to be made from the very beginning.

The case just reported assumed for a period of six months the syndrome of paralysis agitans without tremor. The age of the patient, his gait and posture, the muscular rigidity, and the variability of the reflexes, all pointed to Parkinson's disease, and, although lacking the tremor, I did not hesitate to call it such. The beginning atrophy with exaggeration of all the reflexes, together with the symptoms of medullary disease, convinced me of the fallacy of my first diagnosis, and made the final diagnosis more positive with each succeeding day.

Charcot's disease occurring in a man sixty-eight years of age is a very rare occurrence, and in a cursory examination of the literature on this disease I find no case reported in an individual of such an advanced age. As a rule, amyotrophic lateral sclerosis makes its appearance between the thirtieth and forty-fifth years, and runs a course covering a period of from two to five years, death supervening as the result of medullary involvement.

The etiology of the disease, like that of many of the system-affections of the spinal cord, is still *sub judice*, and nothing occurring in the course of the disease of the patient can add anything to solve this perplexing question. Syphilis, alcoholism, excesses, heredity, spinal injury, all were absent, and the only factor that may have had some influence, if a cause must be found, was the rheumatic tendency of the patient, and to this I cannot subscribe.

At the present time there is a movement, as yet incipient, to class all forms of muscular atrophy under one head, and especially to ignore the autonomy of amyotrophic lateral sclerosis. In formulating a classification, the course and duration of a disease should be given as much weight if not more than the symptomatology. It would be folly to insist that the Duchenne-Aran type, or the Erb type, of muscular atrophy is essentially the same disease as amyotrophic lateral sclerosis, even if the symptomatology were exactly alike. The fact that the former runs a course covering many years, terminating through some superadded affection, generally acute, while the latter always terminates through bulbar encroachment, after a lapse of a few years, is sufficient proof of their complete pathologic dissimilarity.

A REMARKABLE CASE OF THEAISM.

BY JAMES WOOD, M.D.,
OF BROOKLYN, N. Y.

DURING investigations lately carried on to determine the existence of a tea-drinking habit, its frequency and the effects of the constituents of the tea-leaf upon the human body, a very remarkable case was encountered. I had become accustomed to meeting individuals who drank from ten to fifteen pints as their daily amount, but when the case to be reported presented itself it was thought rare enough to report.

Case 306 was a tall blond, twenty-six years of age, who had come to this country from Ireland when quite a young girl. She was married in her eighteenth year to a strong, burly man, much addicted to the use of alcoholic beverages. One year after marriage their first child was born, and from this time she commenced to use tea. Why she should have begun at this particular time she could not explain. At first she said the amount was very small, but the quantity necessary has grown greater and greater. In all, four children have been born to her, and while nursing them she has always kept a quart-pitcher of tea by her side from which she frequently regaled herself. She said that she had become more irritable and cross every year, and found it harder to content herself with her husband and his drinking-habits, and that in consequence domestic infelicities had increased in number yearly. She had also found that tea would take the place of food, and when not particularly hungry, or too busy to prepare meals, she had recourse to the teacup with complete satisfaction.

This is briefly the history of the patient when she presented herself for treatment for, as she said, nervousness and sleeplessness.

At the time of her first visit she had paroxysms of what she termed "cruel and fierce" headaches, either temporal, frontal, occipital, or general, persistant neuralgia of the face and neck, and dull, heavy pains in the lumbar region. She had also attacks of vertigo, mental disquietude and confusion, and was conscious of increasing forgetfulness. After these attacks she would have periods of despondency, alternating with great anxiety, a feeling of impending accident and death, either to herself or children. There would be times when her sleep was restless and troubled; nightmares and dreams were frequent; after which there would ensue insomnia, at times complete, and of several nights' duration. She was very nervous, easily startled, and very prone to be hysterical. The hallucinations usually met with in cases of tea-intoxication were also present in her case. She had at times an almost irresistible desire to look around

or under the bed, because she imagined that some one was in the room. She said that when she stopped to think she "knew it was not so, but that she *must* look and see." When walking on the street there seemed to be shadows on the sidewalk beside her, as if made by some huge animal.

This is a brief detail of the most prominent nervous symptoms so-called. Her bowels were very much constipated, several days elapsing without an evacuation. She had no appetite, was subject to attacks of severe cardiac palpitation, and complained of a sinking sensation at the pit of the stomach. Her menses occurred every three weeks and lasted about eight days, and at this time all of the symptoms were much aggravated.

The amount of the infusion of the tea-leaf drunk by this woman is astonishing, and the case is for this reason by far the most remarkable one in a large collection of tea-inebriates.

When asked how much tea she drank a day, she hesitated, and then said, "Oh, I drink about thirty cups a day." After closer questioning by both my associate, Dr. Alexander C. Howe, and myself, she confessed that she drank five cups before and five at breakfast, but did not know how many during the day, because she drank from a pitcher or bowl, as drinking from a cup was too slow a process and unsatisfactory. She said that her husband, who did not use tea, would let her buy only two pounds a week. From this she could make about seven "pots" of tea per day. The teapot, she explained, had a capacity of two quarts.

Here, then, is a woman who drank on an average twenty-eight pints of the infusion of tea every twenty-four hours, and who said that she could have drunk more had not her husband prohibited such an extravagance. From the history and from her own story the reason for drinking tea in this large amount lay solely in its stimulating effects. From a study of the physiologic action [1] of thein and the essential oil on the system, this is not surprising, nor could a better and at the same time more pernicious non-alcoholic agent be found in common use.

HOSPITAL NOTE.

FRACTURE AT THE BASE OF THE SKULL.

BY ROSWELL PARK, A.M., M.D.,
PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO.

(*Clinic at the Buffalo General Hospital.*)

THE patient who is to be brought before you is a young man who fell on the ice three days ago, striking on the back of his head. Dr. Appell saw him on the ground, and noted a profuse hemorrhage from the left ear. The doctor douched the ear freely with an antiseptic solution, and then made aseptic occlusion of the auditory canal. The patient complained of nausea, and tried to control it till a basin that he called for could be procured. I mention this apparently trivial incident to show that he was conscious after the injury. There was also bleeding from the nostrils, which are now plugged with iodoform-gauze. Early this morning he had a slight headache, but he has none now. He feels like sitting up, but of course this would not be advisable. There is still hemorrhage from the left ear.

The question to be considered involves at once both diagnosis and prognosis as the latter depends largely on the former. Ordinarily, when we have a history of injury, especially of the back of the head, with bleeding from the ears or nostrils, the diagnosis is of fracture at the base of the skull. Nose-bleed may come from a much less serious injury, but bleeding from the ear usually indicates quite serious mischief, though not necessarily fracture at the base of the skull. It is conceivable that the hemorrhage may come from the middle ear or from a rupture of the artery of the drum, on the same principle that rupture of a little vessel in the nose may cause epistaxis. The only reason for deciding against fracture at the base of the skull is that the man feels so well, and that he has no elevation of temperature. But the time for the development of serious symptoms is not yet past. There are many symptoms that are considered characteristic of fracture at the base of the skull that are lacking here, though their absence is no reason for excluding such an injury. There is no protrusion of the eyes, no ecchymosis of the lids, no subconjunctival ecchymosis indicating hemorrhage into the orbit. It is quite possible that these symptoms may develop in the next day or two, and, in that case, there would be positive reasons for favoring the diagnosis of fracture. There was certainly concussion of the brain, and, probably, contusion, as shown by the vomiting.

The prognosis is good. There is no positive evidence of fracture at the base of the skull, and even if that condition exists, not every case is fatal. The symptom to be most carefully watched is the temperature, and this will be noted three times a day. If it rises we shall be apprehensive that our diagnosis, and, therefore, our prognosis, must be revised. In case the temperature should rise antiphlogistic measures would be indicated. We may apply an ice-cap to the head; in many instances leeches have proved life-saving, and I shall direct that if his temperature rises leeches be applied behind the ears. At present we shall simply maintain asepsis about the ears and nose. The danger to guard against is the travelling of infection from the passages outside the cranium into the cranial cavity. If the hemorrhage from the ear is due to a crack of the petrous portion of the temporal bone you can readily comprehend that the same crack may admit germs from without. Even if the fissure and the middle ear are filled with blood-clot, there is ample opportunity for infection of the clot through the Eustachian canal, even if the membrane of the drum be not broken. Bacterial growth may begin in the blood-clot within an hour after the injury, and, after the clot has been broken down by the germs, the same activity may extend to the layer of blood-clot in the fissured bone, and then it is but a step to the formation of a septic embolus in one of the sinuses, and septic sinus-phlebitis results. On account of the prompt application of the proper antiseptic measures in this case I do not apprehend such a succession of events, but you can readily understand what might have happened had not the attending physician acted as promptly as he did, and if, in spite of his excellent treatment, there had been bacteria in the middle ear or Eustachian canal,

[1] American Medico-Surgical Bulletin, September 1, 1894.

which could not have been prevented from developing. Aseptic occlusion of the nasal passages, which we are trying to carry out, cannot be made absolute, because of the contamination of the air through the mouth, but, realizing this fact, we are wise to make an effort in the right direction.

There is another phase of this case to be considered. How is it that a man may have a fracture at the base of the skull and yet be in as good general condition as this patient seems to be? The serious nature of these cases is not due to the crack in the skull. There is no reason why that should be more serious than a similar injury to another bone. The real trouble lies in the danger of injury to and infection of the brain and its membranes. The brain here is evidently not severely injured. So long as there is no marked alteration in the anatomic relations to cause pressure on some part of the brain, and so long as pyogenic germs do not enter, the injury is of comparatively minor importance.

TOXICOLOGIC NOTE.

TOXIC EFFECTS OF TRIKRESOL.

BY CLARENCE O. AREY, C.E., M.D.,
PATHOLOGICAL LABORATORY, WESTERN RESERVE UNIVERSITY, CLEVELAND, OHIO.

DURING some experiments made recently in the laboratory with a flask of toxin of the diphtheria-bacillus I obtained some results that at first seemed strange, but that were afterward explained as being caused by the action of the trikresol contained in the solution. This special flask of toxin was the one mentioned in THE MEDICAL NEWS of July 6, 1895, p. 20, which, for some reason, had decreased in its powers. In ascertaining this reduction in this direction enormous doses, ranging from 10 to 13 c.cm. of the toxin were given. The symptoms resulting were identical in all cases, with very unimportant exceptions.

Three guinea-pigs were injected with this diphtheria-toxin containing 0.5 per cent. of trikresol, and a fourth guinea-pig was injected with a solution of the same strength of trikresol in distilled water. The doses given and the weights of the guinea-pigs were as follows:

The first guinea-pig experimented upon weighed 373 grams and received 11 c.cm. of the toxin mentioned. The second pig weighed 377 grams and received 12.5 c.cm. of the toxin. The third pig weighed 406 grams and received 12 c.cm. of the toxin. The fourth pig weighed 343 grams and received 12.5 c.cm. of a 0.5 per cent. aqueous solution of trikresol. These figures give an average weight of 375 grams and an average dose of 12 c.cm. of the solution, or 0.06 grams of trikresol itself; equivalent to 0.16 grams of trikresol per kilogram of body-weight. This would be equivalent to giving a man of 150 pounds avoirdupois about 150 minims of pure trikresol in aqueous solution. The solutions were in all four cases administered hypodermically.

The symptoms resulting from the injections were as follows:

Within the first three minutes after the injection the animal commenced to tremble. This trembling was accompanied by a peculiar rhythmic motion, commencing at the head and running down to the hind feet, starting very much like the jerk of a hiccough. Putting the hand on the left side of the chest at the same time the heart was felt to have a fluttering motion, in time with the trembling and rhythmic jerk.

About five minutes after the injection the animal commenced to lose control of the hind legs, and a few moments later complete paralysis of these extremities developed. In from one to ten minutes after this the animal commenced to lose control of the front legs, but these extremities were much slower in reaching the stage of complete paralysis. While passing into this stage, however, the animal kept drawing them forward, with a slow swimming motion, in a vain endeavor to regain his feet. At the same time the animal's chin kept dropping lower and lower, till, as he lost entire control of the front extremities, the head rested limply upon the table. This stage occupied about ten minutes, during which time the rhythmic tremors were becoming more severe. Picking the animal up at this stage, the whole body was pertectly limp and flaccid. The animal now lay upon the table in very much the position that the hunter stretches the skin of a small animal on the wall to dry, and remained in this stage for ten or fifteen minutes, when a slight diminution in the severity of the tremor could be noticed. This became less and less severe, till about forty-five minutes after the injection the animal tried to regain his feet, which he succeeded in doing a few minutes later, the tremor still continuing, although slighter. At the end of an hour the tremor was almost imperceptible, and putting the animal into his cage he commenced to eat. No after-effects were noticed.

These experiments would tend to show that trikresol is a very safe antiseptic, as no such quantities as were employed here would ever be introduced into the body in the proportions that are used in antiseptic mixtures.

NEW DEVICE.

A NEW PHIMOSIS-HOOK.

BY G. NATANSON, M.D.,
OF BROWNSVILLE, TEXAS.

IN performing the operation of circumcision, as is well known, the *lamina interna* or *mucosa* of the prepuce must be fixed and put on the stretch, together with the integumental parts, before the foreskin is cut. Among the various instruments used for this purpose the most ingenious and most serviceable are the phimosis-forceps of Levy and of Girdner, the illustrations of which are given in Tiemann's *Armamentarium Chirurgicum* of 1889, pp. 336 and 337, and in some other catalogues of surgical instruments. But these two forceps are not conveniently used together with the glans-guard, as, for instance, the Knox phimosis-clamp or forceps. While the screw of Levy's and the spring of Girdner's forceps tend to separate the opposite parts of the prepuce, the tendency of the guard is to bring them together. Besides, the strong spring of Girdner's forceps may easily rupture the often very delicate prepuce of infants, as, for instance, in cases of ritual circumcision, if not used with great caution, which cannot be expected of every untrained assistant holding the forceps. The serrated surface of Levy's forceps may sometimes not safely enough fix the mucous membrane.

An instrument that I have devised for the purpose in question consists of two double-hooked tenacula, each about four inches long, the lower part of the tenacula being grooved. In the groove passes a slide, ending in a very small cylinder with two notches on its surface. When the slide is lowered (pushed down) the cylinder comes in contact with the hooks, which fit completely into the notches, as is clearly shown in the illustration. The cylinder (c in Fig. B) is about two millimeters high and one-and-a-half millimeters in diameter. The hooks thus being hidden in the notches, the peripheral end of the instrument can be easily introduced into the

FIG. B.

c

FIG. A.

preputial cavity as deeply as desired and moved around, as may sometimes be required for breaking up adhesions, without fear of doing harm to the glans.

After introducing into the preputial cavity the guarded hooks, which I place to the right and left of the glans, the slide is removed and the hooks come in contact with the mucous membrane. Slight pressure is then sufficient to push them through both layers of the prepuce, which are thus put on the stretch simultaneously. The guard is then applied and the operation performed in the usual manner. The same guarded hooks can be easily brought under the remaining portion of the mucous membrane and fix it well enough to facilitate the removal of this portion by the scissors. The instrument is made according to my design by Messrs. Geo. Tiemann & Co., of New York.

MEDICAL PROGRESS.

Perforation of the Bowel by a Fish-bone, with the Formation of an Intra-abdominal Abscess.—MAYLARD (*Glasgow Medical Journal*, vol. xliii, No. 5, p. 350) has reported the case of a tuberculous patient, thirty-four years old, who presented a rounded tumor in the right inguinal region, on a level with the anterior superior spine of the ilium, about two-and-three-quarters inches to the right of the median line. This was tender on pressure, of firm consistence, and could be outlined by palpation, and over it the skin was freely movable. The swelling gradually increased, both in size and tenderness. There was little or no elevation of temperature. There was some tendency to looseness of the bowels. The case was believed to be one of appendicitis with suppuration, and a vertical incision was made over the spot where fluctuation was suspected. About half an ounce of thick, creamy pus escaped, devoid of fecal odor. The forefinger was introduced with the object of opening up what was believed to be a large abscess-cavity situated deeply. As, despite the utmost care, the adhesions surrounding the abscess-cavity were broken through and a communication with the peritoneal cavity established, the incision was enlarged with the view of removing the appendix and thoroughly washing out the peritoneal cavity. The abdominal wall was enormously thickened, in one place measuring three inches. The appendix was discovered at the lower part, being perfectly free and normal. The floor of the abscess was formed by a ragged, thickened mass of tissue on the surface of the colon externally, and a coil of small intestine internally, which were intimately united together. During the manipulations a small fragment of bone was discovered lying loose. The abdominal cavity was irrigated and the wound stitched up, except the lower part, where a drainage-tube was inserted. The foreign body was about three-quarters of an inch long, and had all the appearances of a fish-bone, and on microscopic examination presented numerous well-marked lacunæ and Haversian canals.

Successful Celiotomy in a Child of Sixteen Months with Appendicectomy.—HAUCK (*Medical Review*, June 15, 1895, p. 463) has reported the case of a girl, sixteen months old, still nursing, who, after the ingestion of a small piece of banana and a little meat during the day, was seized at night with vomiting, which continued at short intervals. There was no diarrhea, but the intestinal evacuations contained mucus and blood. On examination of the abdomen a tumor, of the size and shape of a small lemon, was found immediately below the ribs and to the right of the median line. The patient was pale and somnolent; the pulse feeble and rapid; the hands and feet cool; the head warm; and the vomiting had become stercoraceous. A diagnosis of obstruction of the bowel, probably due to intussusception, was made, and operation advised and consented to. Through a median incision, two inches long, from the umbilicus downward, a finger was introduced, and a tumor felt encircled by a coil of intestine. During the manipulation the strangulation was relieved, and the cecum slipped out through the wound. This part of the bowel and the ascending colon were much congested and thickened by edema, the vermiform appendix being as thick as the little finger and ecchymosed. The last was, therefore, removed, the cut edge being inverted by means of three fine silk sutures, and the opening closed completely. The bowel was returned, and the abdominal wound approximated with a line of buried sutures, two deep and two superficial, and appropriate dressings applied. The child reacted well from the operation, and was soon on its way to permanent recovery. The bowels were moved a day after the operation by means of a glycerol-suppository, followed by three one-eighth-grain doses of calomel, given every two hours.

Spontaneous Laceration of the Stomach.—BRAYN and RIDLEY (*British Medical Journal*, No. 1795, p. 1145) have reported the case of a strong, well-nourished woman, thirty-seven years old, who after dinner vomited a small quantity of blood, rapidly became unconscious, and died in about half-an-hour. Upon post-mortem examination the abdominal cavity was found to contain ten ounces of bloody serum, the stomach was much distended, and on the anterior wall at the cardiac extremity was a distinct rent, about one quarter of an inch long, through the serous coat only. The direction of the laceration was downward and to the right. The interior of the organ was filled with coagulated blood, which when broken up was found to contain pieces of imperfectly masticated meat and other material which ap-

peared to be bread. The mucous membrane was free from signs of disease and appeared perfectly healthy, only a slight redness, such as normally exists during digestion, being apparent. The walls of the stomach were thick and strong, and displayed no appearances of degeneration or softening. The diaphragm and muscular walls of the abdomen were also very strong and well-developed, and the remainder of the abdominal, as well as the thoracic organs were normal. The rupture of the stomach is attributed to violent contraction of the viscus upon a mass of undigested food, accelerated by the action of a strongly developed diaphragm and abdominal muscles.

A Case of Severe and Persistent Hiccough.—WIGHTMAN (*Lancet*, No. 3744, p. 1364) has reported the case of a man, fifty-eight years old, who had been having hiccough for forty-eight hours. He was a total abstainer, but was in the habit of drinking much tea. He had smoked half an ounce of tobacco daily for a number of years, and was a very small eater. Chloral and bromid were prescribed at bedtime, but after five hours' sleep the hiccough recommenced. Pressure over the region of the phrenic nerves, at the lower and front part of the neck, controlled the spasm for a short time. Larger doses of chloral and bromid were followed by a quiet night, but the hiccough was worse in the morning. The contractions of the diaphragm were violent and frequent, often one hiccough being represented by five or six consecutive contractions. The hiccough occurred eight or ten times in a minute, sometimes more frequently. A blister three inches square was applied over the region of the diaphragm in front, as well as ice to the nape of the neck and spine. Despite active and assiduous treatment with various drugs, including camphor, belladonna, zinc sulphate, morphin, valerian, and amyl nitrite, the hiccough continued with varying severity for twelve days, and for a time pronounced nervous symptoms were present.

THERAPEUTIC NOTES.

The Treatment of Fetid Expectoration with the Vapor of Coal-tar Creosote.—CHAPLIN (*British Medical Journal*, No. 1799, p. 1371), observing the freedom from pulmonary affections enjoyed by those employed in the manufacture of coal-tar creosote, was led to employ this substance in the treatment of various conditions attended with fetid expectoration. For this purpose he utilized a small chamber about seven feet square by eight feet high, made as air-tight as possible, and in the center of which on a pedestal was placed a spirit-lamp, and over this a flat, open dish into which was poured the creosote. When the lamp was lighted the room soon became filled with the characteristic pungent fumes. The patient sat in the chamber and inhaled the vapor, at first with only a gentle heat applied. As time went on, however, the patient was able to stand the inhalation with impunity. To obviate the irritating and smarting effects of the vapor upon eyes and nose, the former were covered with watch-glasses fixed with adhesive plaster, and the latter was plugged with cotton-wool. A towel pinned over the head and a loose dressing-gown protected the hair and clothing from the odor of the creosote. The first inhalation lasted a half-hour; the latter an hour or an hour-and-a-half. The treatment was repeated daily, and the course lasted from six to twelve weeks. Altogether six cases were thus treated, a seventh being still under observation. Expectoration was facilitated, the quantity at first increasing, but later diminishing and the offensiveness disappearing. Breathing became easier, and the general condition distinctly improved.

The Treatment of Morphin-poisoning with Potassium Permanganate.—HUMPHREYS (*New Orleans Medical and Surgical Journal*, June, 1895, p. 861) has reported the case of a negress, eleven years old, whose mother had given her a No. 2 capsule packed full of morphin, thinking it was quinin. By comparison with a similar capsule the amount taken was estimated at six grains. When seen five hours later the child was collapsed, lying perfectly motionless, with the pupils tightly contracted, the respirations 4 to the minute and sighing, and the pulse hard, full, regular, and 138 to the minute. The girl could not be aroused. Hot water with mustard and other domestic emetics had already been given, but without avail; and also copious drafts of coffee. Strychnin sulphate (gr. $\frac{1}{30}$) and atropin sulphate (gr. $\frac{1}{60}$) were injected beneath the skin, and as soon thereafter as it could be prepared 2½ grains of potassium permanganate were given. In the course of an hour the permanganate was repeated, and in a short while the patient opened her eyes and turned over voluntarily. The respirations had increased to 12 and the pulse had fallen to 110. After the lapse of another hour permanganate was again injected, and gave rise to considerable pain. Soon afterward the child arose from bed and walked across the room to get some water. The improvement thus continued, another dose each of strychnin and atropin and potassium permanganate being given. Ultimate recovery was perfect.

In the Treatment of Lichen Urticatus, NEEBE (*Monatshefte für praktische Dermatologie*, B. XX, No. 12, p. 672) points out that two indications are to be met: (1) relief of the itching; (2) improvement in the general condition and treatment of the associated rachitis. For the itching a 2 per cent. ointment of betanaphthol may be employed, vigorously applied for ten minutes. The general treatment includes principally the correction of digestive disorders. Laxatives, as calomel or tincture of rhubarb, may be given and the diet restricted to simple soups, bouillon, and wheaten bread. Ordinary diet may be resumed after the stools have lost their offensive odor. Internally for the itching the following formula is useful:

R.—Antipyrin . . . . . ℥ss.
Syrup of orange-peel } āā . . f℥j.—M.
Distilled water }

Sig.—One or two teaspoonfuls are to be given at night.

For the rachitis the following may be employed:

R.—Phosphorus . . . . gr. $\frac{1}{10}$.
Cod-liver oil . . . . f℥j.—M.

Sig.—A teaspoonful is to be taken once or twice a day.

SATURDAY, JULY 20, 1895.

COMPETITION AND MEDICAL ETHICS.

WE publish to-day a letter from a valued correspondent to which we are earnestly requested to reply. We do so somewhat reluctantly, because we shall be compelled to leave untouched a number of what we deem errors on the part of our correspondent, and because these discussions are of little use in convincing anybody. Moreover, all such questions almost inevitably and finally narrow themselves down to personalities, the sum and substance of them being: "How much personal honor and sense of self-respect have you, or how much will you sacrifice honor to money-getting and success-gaining? We shall, therefore, warn intending correspondents that we cannot give our space to further letters upon the subject.

If we apprehend our correspondent correctly he criticises or would abrogate the Code of Ethics:

1. Because some men, many men, break it.

2. Because the breakers are not, and cannot be, punished.

3. Because competitton must, he so intimates, make all physicians breakers.

1. Now as to the first point, we cannot see that any rule of social life, of ethics, of business, or of religion, is, *per se*, the worse, or to be criticised, or to be abrogated, because broken every day by individuals, few or many. The question lies behind the sad fact of the breakages, and consists in the fact of the rightness or unrightness of the rule. Does our correspondent think the spirit and injunctions of the Code good? He says he is an "admirer of the Code." Is it the less admirable because many men break it? This assertion of admiration of the Code, coupled with continual carping at it, instead of at its breakers, betrays, at least, a very strabismic "admiration" and a very suspicious allegiance. Would it be well for the profession and for society if the provisions of the Code were obeyed by all physicians? In so far as these injunctions are disregarded and broken, are not both profession and the public the worse, and the worse off? In so far as a physician is a gentleman will he not act from the same spirit as that which inspired the writing of the Code, even if he never read a word or never even heard of that document? We have many times said that the only argument the Code-smashers have is the fact that so many physicians break it, but what asinarian logic is that! This whole argument seems designed finally to end in a resolve of the few sane in a world of fools—they who have escaped wetting by the fool's rain, to hunt up a puddle of the rain-water, plunge in and be happy—happy in a uniformity of foolishness with their grinning fellows. Down comes the question to one of personality: Do you prefer to be among the breakers or among the law-abiding—if you press it—among gentlemen?

2. Punished? The question betrays the sorry confession that, to the correspondent's mind, there is no genuine punishment except an objective one. But except a subjective one there is no punishment for any lapse from the higher ideals of justice, kindness, and honor. So far as one can see, progress in civilization consists in progress in character-building, in the establishing of sentiments within the individual breast, the abuse of which can be "punished" only by one's own conscience and sense of degradation. If one has not such sentiments and character, he may be happy in his life, and happy in choosing as his companions those that are like-minded, but he will find that others are different-minded and that they will choose different companions. And this, we suppose, includes the idea of punishment of our correspondent, the criticism that medical societies do not exclude the Code-breakers—the majority of the members of which are sometimes even breakers.

Supposing it to be so, does that supply sufficient reason for not preserving one's own self-respect? Would it not be better to work for the execution of the Code rather than for its abrogation? Supposing the Code were abolished, what earthly difference could it make in the facts? Gentlemanliness would still remain admirable, and all the Code-smashers would only make it more admirable, whilst one would still be compelled to choose his friends, or would be chosen by them, then just as now. When the medical societies and associations become so degraded that a majority of their members, individually and officially, habitually disregard those ordinary principles of kindness, honor, courtesy, and good breeding, upon which the poor Code is founded, then so much the worse, and gentlemen will not wish to be members—just as many men already do not care a button for membership in some medical societies. Down to a personality again comes the discussion: Do you prefer to be of the breakers or of the practisers of ethical conduct? If of the latter class you certainly cannot care whether there is a Code or not; you will obey it whether objectively the rule of societies, or whether smashed to smithereens by all societies. As to "punishment," we have no sort of doubt that the supposed breaking of the Code will sooner or later be found to be only a breaking of the breaker. As the Code prescribes nothing but simple common courtesy, benevolence, and self-respect, the Code will remain quite unbroken though the whole world deludes itself into the belief that it breaks it.

3. Competition will certainly make all those physicians breakers of the Code who find no inner reason for not breaking it. But the fundamental question lying behind this, and, indeed, behind all three criticisms, is: Does it pay to break? And this question, of course, is followed by the counter-query: What do you consider "pay?" That would involve a sermon on the value of money and success; on the idiotic overvaluation of both by the little-souled and the mean-minded. If you think them worth the price some pay for them, for Heaven's sake buy, or beg, or steal them. Sensible men know better, and nothing but bitter experience will teach you better. If you think that at the end of your life you will, by breaking, be more honored by your fellow-men, more satisfied with your life-work, that you will leave the world better for your life of breaking, then look a bit to your logic—we think you deceive yourself—but if you conclude so, then, by all odds, go ahead at the breaking business. But if it be said that despite average ability, proper education, and due diligence, one cannot, while obeying the spirit and even the letter of "the Code," make a comfortable living, and raise one's family decently and honorably, then, fortified with the testimony of thousands of lives so lived, we can only say, *It is a lie!*

As to our correspondent's division of life and character into hard-and-fast compartments and divisions, with no interactions and influences—this labelled medical practice, another ethics, that law, the other religion—well, this is simply poor and wearisome nonsense. Ethics, principles, honor, religion, if a man actively have these qualities, are not "totally different things;" they are only multiple phases of one indivisible psychic reality; each interpenetrates and influences the other, and from them, as a composite whole, spring the motives that incite and the methods that realize all conduct.

EDITORIAL COMMENTS.

Accidents Due to Railroad and Trolley.—Chicago has been called the "most blood-guilty city on earth," because of the great number of lives annually lost through railroad-accidents. The Chicago Commissioner of Health reports, in 1894, 354 deaths from this cause, and he blames the "grade-crossings" for the mortality. In Philadelphia the number of deaths from railroad-accidents recorded by the Coroner in the year 1894 was 236; in 1893 it was 216; and in 1892, 208. For the six months ending July 1, 1895, 106 cases are reported. In Chicago nearly 50 additional fatal railroad-accidents were not recorded as such, but were returned to the Board of Health under the head of "fracture of the spine," "surgical shock," etc.

Of the 354 fatal accidents occurring in Chicago, about 45 were from street-cars, and the balance from steam-railroads. Of the 236 deaths in Philadelphia in 1894, 67 were from street-cars; and for the six months of 1895, 55 deaths on the Coroner's books are charged to the street-railways, including the trolleys. Many of the cases investigated by the Coroner occur among the employés of the road, and are included in these statistics. The city of Brooklyn has but 70 deaths from railroad-accidents recorded on its Coroner's books for the year 1894, and yet during the late railroad-strike in that city its surface trolley-companies were accused of great recklessness and gross disregard for human life, and the Coroner's clerk in a letter to us has limited his figures to the *records* in *his* office.

Chicago has 3000 streets crossed at grade by steam-cars. In Philadelphia we have not quite so many grade-crossings, and yet several hundred more than we ought to have. The trolleys have added a considerable number of deaths to the mortality-list, but the grade-crossings continue to furnish the greater number. While the trolley is deadly on the one hand, it is on the

other hand a therapeutic agency of no little value, and must exercise a beneficial influence upon the life and health of the community. What was formerly only possible to the wealthy, namely, a ride into country, can now be indulged in by the poorest inhabitant—and what can be more health-giving, after the hard work of a hot day, than a long ride in an open car out into the surrounding country? The young people have trolley-excursions instead of dancing-parties. The children of the poor districts are taken on an airing instead of sweltering in hot rooms, and thousands are benefitted that never were before.

While we bemoan every unnecessary death, and believe that every precaution should be taken by the railroad-companies to prevent accidents, yet we feel that the newspapers are more interested in the sensation created by their records of trolley-deaths than in the real welfare of the people. If they would as faithfully and as graphically record each death from diphtheria, or typhoid fever, or tuberculosis, deaths as clearly preventable as trolley-deaths, and due largely to neglect on the part of both the individual and the community, they would do a good that would be wider-reaching and that would aid in materially lessening the mortality-rate of our city.

Deaths Among Medical Men.—In the June number of the *Brooklyn Medical Journal* DR. J. L. KORTRIGHT writes of the causes of death among medical men, basing his conclusions on the record of deaths of 450 physicians occurring in the cities of New York and Brooklyn during the years 1884–1892. He found the average age at death to be 54.6 years. This is rather a high average, although compared with that of Presbyterian ministers (sixty-nine years) it is quite low. Clergymen have always had a greater longevity than most other people, while doctors are ranked with brewers, saloon-keepers, and butchers.

Three per cent. of the deaths were from suicide—a ratio somewhat higher than is found in the population generally, but not so great as Dr. Kortright states, as he has reckoned on the entire male population, whereas he should have considered only males between the ages of twenty-one and sixty-five.

The diseases connected with sclerotic changes in the arteries, namely, those of the heart and kidneys, and which Dr. Kortright groups under the term "arterial sclerosis," caused 35 per cent. of the deaths, and he therefore terms this group the "doctor's disease." No attempt is made to show whether or not medical men are more liable to die from such diseases than other professional men, yet the warnings given are timely and worth heeding: "When you find your arterial tension increasing, your temporal artery becoming tortuous, your radial hardening, ... know that old age is upon you, curb your ambition. Be content with a small practice. Reduce your expenses. Give up your night-work. Decline confinements. Take a long vacation in summer." How many physicians who enjoy a fair competence persist in doing work that overtaxes them and which they could readily assign to others. If the doctor does not care about his own health, he owes it to his patients that he should not overwork himself. Can a medical man do honest work when after attending a confinement at night he visits his outside cases in the morning, returns at 2 o'clock, takes a hurried lunch, and treats office-patients until 5 or 6 o'clock and has another batch from 7 to 9, with perhaps an hour of hospital-work and an hour of teaching fitted in somewhere durthe day. This picture is taken from real life. Such a man can afford to decline confinements, need not have evening office-hours, and ought not to do charity-work in hospitals.

Medical teaching will some day, we hope, be a specialty in itself, just as teaching in other departments of knowledge already is. A teacher cannot do his duty to his pupils and at the same time attend to a large practice and hospital-work besides. As his work increases the physician should confine himself more and more to special cases and allow his assistants and younger colleagues to assume some share of the burden. He should mingle more with the world around him, with his family, and even take a part in the affairs of State. Why should not the teachers and wardens of health show the world by their own lives how to live. Doctors owe it to themselves and to the community to use every means to reduce their own mortality-rate.

Report of the Department of Health of Chicago.—A very interesting and valuable report is the one just issued by the Department of Health of the City of Chicago for the year ending December 31, 1894. The growth of these departments in large cities and the variety of duties assumed render this work important, especially if recorded in a scientific manner. The Commissioner of Health, Dr. Arthur R. Reynolds, gives a summary of the work in the first thirty-six pages, and then follow two papers, one on "The Water-Supply of Chicago" and the other on "Needed Sanitary Legislation."

The tables of deaths are very complete and present some new and valuable features. Twelve per cent. of all the deaths reported took place in hospitals and other public institutions. The total death-rate of the city was 15.24 per 1000—the lowest death-rate, be it observed, of any city in the world with a population over 200,000. The other lake-cities, Detroit, Milwaukee, Cleveland, and Buffalo follow Chicago very closely, and the commissioner suggests the influence of the Great Lakes as being important in this connection.

The work during the smallpox epidemic, according to the report, was enormous. The returns showed that 59 per cent. of the persons attacked were unvaccinated; that nearly 30 per cent. of the school-population required vaccination. Over 1,000,000 free vaccinations were performed in a few months.

The increase and decrease in diseases is graphically shown, and the period covered is long enough to draw conclusions from it. Carcinoma has increased greatly, both in relation to the population and to the number of deaths from other causes. From 1851 to 1865 the deaths from carcinoma in 10,000 of the population averaged about 0.50, from 1866 to 1890 it increased to 2.80, and from 1881 to 1894 to 3.90. For Philadelphia the rate in the past few years has been over 5 in 10,000 of the population.

Whether carcinoma shall be proved contagious or not, the recommendations of the Commissioner in regard to the disinfection of dressings and discharges are worth heeding.

The other features of the report are all worthy of special study and are very suggestive. Factory-inspec-

tion and smoke-nuisance inspection are portions of the work of the Health Department of Chicago.

The diseases reported as generally diminishing in the mortality-rate are tuberculosis, croup, diarrhea, diphtheria, dysentery, malarial fevers, measles, puerperal fever, scarlet fever, typhoid fever, and pertussis, while nephritis, bronchitis, carcinoma, cholera infantum, heart diseases, nervous diseases, and pneumonia are increasing.

In Philadelphia typhoid and tuberculosis furnish a decreasing death-rate from year to year, while pneumonia, bronchitis, and diseases of the heart return a higher mortality each year. In this connection it were well if our own department of health, would in its reports, compute the rates on the number of inhabitants, as has been done in the Chicago report.

The Influence of Removal of the Ovaries upon the Bodily Metabolism.—While there are few organs whose function is absolutely essential for the maintenance of life, there is probably none whose functional activity is not without influence upon that of other organs and structures. Of the validity of this proposition we have of late years had an abundance of evidence. Perhaps the most conspicuous illustration is to be found in the thyroid gland, to whose absence or atrophy or disease is attributed the group of diseases comprising myxedema and cretinism and perhaps also exophthalmic goiter. One practical outcome of a recognition of this inter-relation resides in the therapeutic employment of preparations of the thyroid gland of one kind or another. Clinical observation has shown also that the ovaries have a not insignificant influence on the metabolic processes of the body. Thus over and above the changes, psychic and physical, that are at times observed at the menopause, occurring naturally or induced artifically by removal of the ovaries, it has been shown that the rather uncommon disease, osteomalacia, will in many instances yield to the operation of oöphorectomy. An additional contribution to this interesting chemico-physiologic subject has recently been made by CURATULO and TARULLI (*Centralblatt für Gynäkologie*, 1895, No. 21, p. 555), who report the results of a series of observations upon the metabolic changes that follow removal of the ovaries. After having fed dogs with food so adjusted in quantity and quality that a fairly unvarying amount of nitrogen and phosphates was excreted, it was found that after removal of ovaries, the other conditions remaining the same, the amount of phosphates eliminated was diminished considerably for some time, the amount of nitrogen undergoing little change. The inference is drawn that this diminution in the excretion of phosphates is to be attributed to the lessened oxidation of the phosphorus present in the tissues in organic form, and which in combination with earthy bases is in health deposited in the bony structures as calcium and magnesium phosphates. In this way, it is believed, is to be explained the improvement that follows removal of the ovaries in cases of osteomalacia.

Misrepresentation of Professional Opinion.—Some time ago the American Humane Association addressed a circular to a large number of prominent men, teachers, editors, professors, ministers, and physicians as to the advisability of illustrating in the public schools physiologic truths and teachings by vivisection-experiments. A pamphlet of the replies has been published, and among them we find but four from men having the degree of M.D. Of these four three are against the practice of vivisection-experiments before children. Two of these medical men are editors, and the other two are non-practising physicians. One of these latter thus writes:

"I certainly think that children and everyone ought to be familiarized with the sight of blood, the pangs of disease, and the solemn event of dying. Death and pain should not be concealed; they are the greatest of all educators; for they alone teach us the value of life in its highest measure.

"The whole tone of your circular is, in my opinion, contrary to the spirit of true education."

We wish first to protest against these atrocious sentiments *per se*, and secondly against them as at all representative of the opinion of the profession—of the *practising* physician. Any clinical experience with disease, with suffering persons, instils into normal hearts a sentiment that shudders with horror at the thought that "children should be familiarized with the sight of blood, the pangs of disease, and the solemn event of dying." This is simply hideous, and we did not wish to let the opportunity pass without denying that this is medicine or medical opinion. Why did the instigator and editor of this pamphlet not secure the opinions of representative and practising physicians upon this question? Was it the secret desire of antivivisection extremism to stigmatize the medical profession with such a wretched travesty of its genuine feeling?

Purulent Parotiditis Due to the Typhoid-bacillus.—The localization of the bacillus of typhoid fever in the secondary lesions of the disease has been demonstrated in a considerable number of instances. The micro-organisms are naturally not to be looked for in the lesions dependent upon intercurrent affections. Among the rarer complications of typhoid fever is inflammation of the parotid gland. It is possible that in some instances this may arise by invasion through Stensen's duct, while in others it may be due to metastatic deposit of typhoid-bacilli through the circulation. Of the second mode of origin an interesting example has recently been placed on record:

JANOWSKI (*Centralblatt für Bakteriologie und Parasitenkunde*, Band xvii, No. 22, p. 785) has reported a case that presented itself for post-mortem examination with a clinical diagnosis of hemorrhagic nephritis of unknown origin. The patient had been ill for seven weeks with febrile symptoms. During the last week a painful swelling appeared in the region of the right parotid gland, but palpation failed to detect the presence of pus. Upon post-mortem examination the intestinal lesions of a recent attack of typhoid fever were found. On section the right parotid gland was found infiltrated with pus, bacteriologic examination of which disclosed the presence of typhoid-bacilli in pure culture.

Gonorrhea Among Convicts.—Of 230 convicts recently examined in the State of Pennsylvania, 156 acknowl-

edged having had gonorrhea once or oftener. Of 500 examined in 1894, over 200 confessed to having had an attack of this disease. Of those who denied infection it is probable that many were not telling the truth. While these figures are obtained from a class that it would be expected would be given to debauchery, yet the prevalence of gonorrhea in all classes of life is excessively great—how great it is impossible to learn, though one need not have a very large experience with worldly men to form an opinion. Statistics on this question are badly needed.

The Bicycle vs. the Horse.—In many small towns the bicycle has taken the place of the country doctor's buggy. In the western part of Pennsylvania, up to ten years ago, doctors were compelled to make journeys over a considerable distance of territory, but to-day every village has its one or two physicians, and the suburban and interurban trolleys have brought the farmhouse quite near, so that the young doctor settling in a small community will be able to forego the expense of keeping a horse, unless he goes West, where, on account of the bad roads, two and three horses are often required in a small practice.

REVIEWS.

TRANSACTIONS OF THE ANTISEPTIC CLUB. Reported by ALBERT ABRAMS, a Member of the San Francisco Medical Profession. Illustrated. New York: E. B. Treat, 1895.

ALAS, for the microbe—the real serious microbe—the one that "Dr." Radam kills with his club, when medical men who have been his discoverers, who have elevated him to position and place, begin to make fun of him. Could Columbus have ever regarded America as a joke, or could we conceive of Morse splitting his sides over the electric telegraph? And so one starts at a disadvantage in making fun over serious medical problems, and expecting the serious Doctor to immediately die laughing. Dickens, in "Bob Sawyer," was more of a success than most of his imitators, and now the day of that kind of student has passed, and he is almost paleolithic and unrealizable. The "Antiseptic Club," however, has no designs upon the risibles of students, but aims at producing a series of smiles on cheeks furrowed by thought, and night-bells, and lips compressed with caution, responsibility, and the fear of inhaling germs. And these lips will never curl the right way at a satire of their own peculiar methods or a joke on their pet hobbies; but, after all, it is unsafe to say what men will laugh at. The point we miss may penetrate the anatomy of a brother and elicit a yell, while we sit silent.

One can smile at the straightening of the Leaning Tower of Pisa with "testiculin," or the timid Doctor who resorted secretly to the juice of a lion; or he who became a brilliant extractor of cataract after using extract of cats; or the man who used to be a gentleman till he tried "porcine fluid" and stole cases and rose to eminence. And there is much that is funny in the dissertation on Peyer, "the memory of whose name was confined to the unhallowed intestinal walls," or the celiotomist's method of advertising, and Smith's successful cough-mixture that gave an expectorating cup with each bottle, and a bed-pan with the pills.

But these are not the cream of the book extracted with a separator. Oh, no! The reader must read for himself the *Antiseptic Club* and look at its funny pictures and find his own jokes to laugh at, and grow solemn and silent when his own corns feel a sudden and heavy tread.

DIFFICULT LABOR. A GUIDE TO ITS MANAGEMENT FOR STUDENTS AND PRACTITIONERS. By G. ERNEST HERMAN, M. B. Lond. F.R.C.P. Pages 443, with 162 Illustrations. New York: William Wood & Co., 1894.

DYSTOCIA, unfortunately, is too often to the ordinary practitioner of medicine practically an unknown quantity. As long as Nature decrees a normal sequence of events he prides himself upon his ability as an accoucheur. Let there exist, however, some disturbance of the fundamental principles underlying eutocia, and the self-estimated "skilled" accoucheur rapidly degenerates into a demoralized attendant, absolutely unable to cope with the problem presented. While such a state of things exists such able books as the one under review cannot be too cordially welcomed. The high standing of the author and the excellent quality of his previous work at once insure a respectful and sanguine reception of his later work. As we glance over the subject-matter of the volume we find that, while not arranged in any systematic order, all of the essential conditions giving rise to difficulty at the time of parturition—with possibly one exception—have been ably presented. If placenta prævia be considered worthy of mention as a complication of labor we cannot see why puerperal eclampsia should be denied this honor. The one is as much a portion of dystocia as the other, although neither is exclusively confined to the time of parturition at term, and, in our opinion, both would properly be treated as abnormalities of pregnancy. The chapter on pelvic contraction is excellent and exhaustive, and the illustrations throughout the book are instructive and well selected. The indexing is complete, the type clear, and the text explicit.

THE PHYSICIAN'S GERMAN VADEMECUM. A Manual for Medical Practitioners for Use in the Treatment of German Patients. By DR. RICHARD S. ROSENTHAL. Part I. Gynecology and Obstetrics.. Pp. 177. Price $2. Part 2. General Practice. Pp. 268. Price $2. Chicago: The Rosenthal Publishing Company.

THIS publication should prove useful to physicians whose work lies to any extent among German-speaking people, and who are not sufficiently grounded in that language to readily learn the facts and clearly give instructions in cases occurring among a not inconsiderable proportion of the population of our large cities. The subject-matter is arranged in questions, which have, as far as possible, been so constructed as to require either *yes* or *no* in answer. While this arrangement is most convenient it has the disadvantage of making the questions "leading." The pronunciation is indicated by the marks in common use, and is satisfactory as far as

it is possible to thus indicate the sounds of German words. Proper pronunciation in any language is only to be acquired through the sense of hearing. Both the working and the literal meaning of every sentence is given. In addition, rules and examples bearing upon forms of German construction have been introduced, so that the book is not without use for persons even totally unacquainted with the language. The drawback to the practical utility of this work, as of all others of its class, is the difficulty of always at once finding the sentence one wants, or the necessity of memorizing the whole. As an adjunct to the thorough study of German it should, however, find a wider field of usefulness.

TEXT-BOOK AND MANUAL OF PRESCRIPTION-WRITING, with a List of the Official Drugs and Preparations, and also Many of the Newer Remedies Now Frequently Used, with Their Doses. By E. Q. THORNTON, M.D. Ph.G. Pages 334. Philadelphia: W. B. Saunders, 1895. Price, $1.25.

THIS valuable manual fills a special place in medicine, and will be peculiarly of service to the younger men in the profession to whom the art of prescription-writing is still more or less of a mystery. In looking through the book there appear but two objectional features, and even one of these may be queried. While it is perfectly proper to present sample prescriptions for the purpose of teaching, the learning of formulæ for specific purposes cannot be too highly deprecated. We fear that many of those into whose hands this book must fall will, from the multiplicity of the formulæ, be tempted to memorize and ignore the higher object of the author. The graver defect is an inconsistency. While strongly recommending the adoption of the metric system, and while giving rules for the conversion of other systems into this, the author gives all of his formulæ in the system in vogue in this country. We would suggest that in the next edition the French method might be put on an equality with the elder system in the sample formulæ in the book. The tables of solubility, doses, and incompatibility are valuable.

TRANSACTIONS OF THE NEW YORK STATE MEDICAL ASSOCIATION FOR THE YEAR 1894. Vol. xi. Edited for the Association by E. D. FERGUSON, M.D. Published by the Association.

THIS handsome octavo volume of 750 pages, with its valuable and varied contents, is a distinct credit to the body from which it emanates, and bespeaks the high scientific character of the Society's membership. It would be difficult and perhaps invidious, even were there space, to select from among the forty-five communications that principally constitute the *Transactions* any for special comment or criticism. In scanning the pages of the volume we have, however, been struck by the following, which we can merely mention: An elaborate memoir on "The Differential Diagnosis of Traumatic Intra-cranial Lesions," by Dr. Chas. Phelps; a "Discussion on Tuberculosis," participated in by Drs. H. M. Biggs, E. K. Dunham, E. G. Janeway, L. F. Flick, J. H. Huddleston, J. D. Bryant, W. H. Park, J. G. Truax; "Some Recent Studies on the Communicability and Treatment of Diphtheria and Pseudo-diphtheria," by Dr. W. H. Park; "A Practical Study of Serious Abdominal Contusions, with a Clinical Report of Twenty-one Cases," by Dr. T. H. Manley; "Intestinal Anastomosis, with the Report of a Case," by Dr. F. H. Wiggin; "Brief Comments on the Materia Medica, Pharmacy and Therapeutics of the Year Ending October, 1894," by Dr. E. Squibb.

A GERMAN-ENGLISH MEDICAL THESAURUS, OR TREASURE OF SINGLE AND COMPOUND MEDICAL WORDS AND TERMS, WITH DIALOGUES, IDIOMATIC PHRASES, AND PROVERBS, ETC., AND GERMAN AND ENGLISH INDEXES, FOR PHYSICIANS AND MEDICAL STUDENTS. By REV. HENRY LOSCH, M.D. 8vo, pp. 323. Philadelphia: Published by the Author, 1895. Price, $2.50.

THE need for a good modern, working German-English medical dictionary has long been felt, and this the present work will in large measure supply. It has been written by one familiar, through education and experience, with the wants of students of language, and especially medical language. The book is divided into three parts. The first and second include a systematic presentation of single and compound medical terms in their various relations, and to this 146 pages are devoted. In the third part are contained dialogues, the declensions, and a complete list of irregular verbs; while 136 pages are given up to an index of German and English words and medical terms, to the number of about 20,000, arranged alphabetically.

The work has been well done and is complete within its obvious limitations. It should serve not merely as a word-book, but as a useful aid to the comprehension of a language which is a most important medium of scientific communication.

MIKROSCOPIE UND CHEMIE AM KRANKENBETT.

CLINICAL MICROSCOPY AND CHEMISTRY. By DR. HERMAN LENHARTZ, Professor of Medicine and Director of the Hospital at Hamburg. 2d edition. 8vo, pp. xv, 331. Berlin: Julius Springer, 1895. Price, 8 M. ($2.00).

THIS little book is the outcome of the author's teaching-experiences in connection with the medical clinic at Leipsic. It does not aim to be exhaustive, but deals succinctly and clearly with such matters as are likely to present themselves in the every-day work of the clinician. The first edition was disposed of in less than two years, and this, the second, has been revised and amplified. After an introduction detailing the apparatus and adjuncts necessary for clinical microscopic and chemic examination, the following subjects are considered in detail: (1) vegetable and animal parasites; (2) the blood; (3) the sputum; (4) the secretions of the mouth and the gastric and intestinal contents; (5) the urine; (6) fluids obtained by puncture. The work is illustrated with sixty-three cuts in the text and three admirably executed colored plates. It commends itself as a safe guide and useful companion for student and practising physician.

INDEX OF MEDICINE: A MANUAL FOR THE USE OF SENIOR STUDENTS AND OTHERS. By SEYMOUR TAYLOR, M.D., Member Royal College of Physicians, Senior Assistant Physician to the West London Hospital. Large 12mo, pp. 794 and xii. Cloth, $3.75 Philadelphia: Lea Brothers & Co., 1894.

THIS volume is a condensed practice of medicine, and as such may fulfil its chief object, of aiding students preparing for their final examinations. We are inclined to believe, however, that its usefulness will be limited, for it will help least those who need it most, and those whom it could help will not need it. The statements and expositions contained in the book are good and reliable so far as they go; the weakness of the work lies in the omissions. Thus, in the treatment of typhoid fever the use of the cold bath according to the method of Brand is not even referred to; nor under diphtheria is the subject of the antitoxin mentioned. Space is devoted to typhlitis and perityphlitis, but not a word is said of appendicitis. No description is given of the modern methods of examination of the blood or gastric contents. We further fail to find descriptions of akromegaly, syringomyelia, and Morvan's disease.

CLINICAL LECTURES ON THE PREVENTION OF CONSUMPTION. By WILLIAM MURRELL, M.D., F.R.C.P. London: Bailliere, Tindall & Cox, 1895.

NO subject is more important than the one treated in these lectures, and the prevailing views are clearly and concisely set out. We differ from the author in placing more stress upon the physical education of the individual than upon the measures adopted to prevent contagion, though the latter are, of course, of considerable importance.

We are glad to see that the author believes that "forcible legislation (on the subject of notification) is a mistake unless backed up by popular opinion."

Dr. Murrell wisely calls attention to the dangers of travel on land and sea from being shut in close, ill-ventilated apartments in company with a tuberculous fellow-traveler, or following the use of the apartment by such a one. Effective measures to prevent this means of contagion are within the reach of legislation, and such legislation might well be adopted and enforced.

LECTURES ON HYGIENE AND SANITATION. By SENECA EGBERT, A.M., M.D., Professor of Hygiene, Medico-Chirurgical College. 8vo., 177 pages. Philadelphia: Franklin Publishing Co.

DR. EGBERT has succeeded very well in accomplishing the task that he states in his preface was in view in the preparation of his book, namely, to furnish a syllabus of his lectures, and at the same time sufficient treatment of the various topics to make it of value to others. The extended and extending field of hygiene has been well considered, being naturally presented in its relations to medicine. It is often overlooked that the important department of public hygiene has an engineering aspect, but it, of course, is not the function of this book to consider that phase. In the more technical features of the science Dr. Egbert has consulted the recent manuals, and thus has kept the work up to date. It is well written and well printed. We regret that it contains no index and only a very brief table of contents.

CORRESPONDENCE.

COMPETITION AND MEDICAL ETHICS.

To the Editor of THE MEDICAL NEWS.

SIR: I dislike disputes, and especially this one, but I trouble you with this letter merely because I would like to see discussed in a dignified manner the real difficulty of the question as regards medical ethics. It is always omitted or evaded. The two things that to my mind militate against the Code of Ethics are:

a. Competition involved in the practice of medicine as a means of gaining a livelihood.

b. Total absence of any provision for effective punishment against infringement of the Code.

There is no comparing of the practice of medicine and the rules that may guide it with such totally different things as common ethics, religion, and law. In not one of these, so far as I can see, does competition enter to the slightest degree. Ethics has to do solely with private conscience, and as soon as it widens out enough to affect one's neighbors it has to do with law or government (always, however, with restraining penalties attached). A man may lie or not to his neighbor; it is a matter of his own conscience and maintenance of his own reputation. If he steals from his neighbor the law steps in and punishes him. Ethics says "thou shalt not lie; but if you do, settle it with your own conscience; if you become known as a habitual liar, you may lose in the long run; but whatever you do, you are always your own free agent, under the constraint only of your own individual conscience. You are not competing with anybody but yourself."

The ethical ideal is a variable thing. Not many approach the ethical ideal of the early Christian martyrs. The ethics of the Hottentots differs from that of the North American Indians. The ideal of ethics is a personal, an individual ideal, and largely a matter of education. Its mandates will be followed, therefore, solely in accordance with the view the individual conscience takes. Another may consider wrong what I consider right, and *vice versa*, and each will act accordingly. One may consider it wrong to take a patient from another physician; the other, reasoning from another standpoint, may consider it quite legitimate; for it is solely a question of personal competition. Each will act, therefore, in accordance with his own particular view of the ethics of the case. If by so doing one injures himself, that is all right, he then has only himself to blame; but if by his act he injures the other he should be punished, and the question ceases to be one of pure ethics, and becomes one of law. And that is my contention—that the Code of Ethics, to be effective, should be made after the manner of a law, with penalties attached; for as a mere expression of ethics it loses its force, as ethical questions are, to a large extent, controversial. The field of ethics is a broad one, and ranges all the way from the law of self-preservation at its lowest point to heroism and martyrdom at its highest. A child is caught in a burning house; two men with their families stand outside. It is certain death to enter the house and try to rescue the child. One man says, "I will not go; my family and my own little ones are dependent upon me and are first in importance to me." (Law of self-

preservation.) The other man says, "I will go in and try to save the child." (Heroism.) He is killed. Which was the better ethically? Was not each right, reasoning from his individual standpoint?

We admire the hero, but we are not justified in despising the other. One soldier leaves all and rushes to death in battle (admirable); another thinks of his home and its need of him (I am not referring to the personal coward who merely runs on account of personal fear) and sends a substitute to the front (not very admirable, but certainly not despicable, either). Both soldiers may be entirely right; but if the government really wants the second man to fight for it, the question is taken out of the sphere of controversial ethics and lifted into that of law; the man is compelled to go to the front or be severely punished in some way.

I shall not even speak of religion and its tenets: that is so absolutely a matter of private opinion that I never for one moment suspected anyone of imagining that religious truths and beliefs were to be compared with any human code. Religion is a matter between a man and his Creator; the Code of Ethics is a rule of expediency between men. Pray, where does competition enter in a man's religion? A Jew and Gentile may live most amicably together, but in their bartering (competition) they may wrangle like the Kilkenny cats.

As an admirer of the Code of Ethics, I do wish it were discussed more intelligently and practically by its staunch supporters. As a pretty piece of ethical writing, it is all right; as an effective rule for the profession, it is valueless for the reasons given.

Sincerely yours, M.

LAW FOR THE PREVENTION OF OPHTHALMIA NEONATORUM.

To the Editor of THE MEDICAL NEWS,

SIR: In view of the recent attempt of the Legislature of Pennsylvania to meet the wishes of many physicians by passing a law protecting professional confidences of medical men, readers of THE NEWS note with interest what it has done for those who desired legislation to combat the ravages of ophthalmia neonatorum.

The law on the subject just passed and printed in THE MEDICAL NEWS, July 13, p. 55, contains several blunders which prevented its indorsement by the College of Physicians of Philadelphia, after it had been fully discussed by both the Council and the College, and which should have been eliminated before the bill was passed. The omission from Section 1 of the (probably intended) article "a" before the words "legally qualified practioner" (*sic*, in the copy of the law sent out from the State Department—practitioner evidently meant) robs part of the law of its obvious significance. Then the duty of notification in writing is put upon a "midwife or nurse or other person." This might mean a bed-ridden mother with only a neighbor to help her, and it is rather hard on those who cannot write.

Sections 2 and 3 are probably inoperative because no money-provision is made for carrying out their mandates. If operative, they are otherwise defective, for Section 1 does not fix a time within which the Health-officer shall do what he is commanded (the word immediately being too vague); and Section 3 commands the Health-officer to furnish copies of the Act to those who are "known to him" to act as midwives or nurses—and how may that be ascertained, in case complaint were lodged against him for neglecting his duty? Then, again, how much time has he to do this in? And, finally, when a Health-officer sends out his "directions for the proper treatment" of ophthalmia neonatorum, shall he give the treatment rationally, or homeopathically, or eclectically, or hydropathically, or physio-medically? or will faith-cure or Christian science teachings stand for a discharge of his duty? or must he furnish all methods, and let each "midwife or nurse or other person" select?

It is a pity, after all the effort made by those who would check the progress of ophthalmia neonatorum, and all the resolutions of County and State Medical Societies, that they should get nothing from the Legislature more plain, practical, and effective than this law.

Yours truly,

CHARLES W. DULLES.

SOCIETY PROCEEDINGS.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Seventeenth Annual Meeting, held at Rochester, N. Y., June 17, 18, and 19, 1895.

(Concluded from page 55.)

THIRD DAY—JUNE 19TH.

DR. T. MORRIS MURRAY, of Washington, continued the discussion on "Tuberculosis of the Upper Air-passages." He related that his experience with lactic acid in the treatment of laryngeal and pharyngeal ulceration had been on the whole disappointing, though good results were occasionally observed. One case had remained healed for five years.

DR. INGALS thought that in an equal number of cases operated on and not operated on, the latter would show more cures, presupposing the usual topical treatment. He has seen ulcerations heal under lactic acid without curetting. It is of doubtful propriety to cut away large masses of tissue when there is deep infiltration. Iodin trichlorid has been of great value, used in a solution of gr. i–ij to the ounce. Cocain depresses the nervous system, and he prefers a mixture of tannic and carbolic acids with morphin.

DR. DALY had obtained the best results with iodoform, with which he saturates the patient, using also creosote in large doses, and inhalations, together with special attention to the diet.

DR. WRIGHT expressed skepticism as to the possibility of curing laryngeal tuberculosis. Of course cases will occasionally heal under curetting and lactic acid. He thought that too much attention had been given to one single etiologic factor. The disease may cause no symptoms whatever, even when the deeper parts are involved. The cases reported cured have been in the first stages of the disease.

DR. SHURLY added that he had used Dr. Ingals' sedative formula, but had had great difficulty in making a permanent solution of its different ingredients. He therefore used them separately. Creosote is a good disinfectant, but he has been disappointed in the results from its internal administration. He could not see how it was of any use to curet a few ulcerations when there were others present in accessible localities.

DR. A. B. THRASHER, of Cincinnati, read a paper on

NECROSIS OF THE MIDDLE TURBINATE.

He said that while the lower turbinate was more frequently inflamed in acute rhinitis than the middle, the position of the latter with reference to the orifices of all the accessory sinuses was such that they were easily closed up when the bone became inflamed and their mucous contents became purulent.

Ethmoiditis is a frequent disease, but middle-turbinate necrosis is rare; although there is no *à priori* reason for this rarity. Given a case of ethmoiditis and a polyp springing from under the middle turbinate, the conditions are certainly favorable for the development of necrosis of the latter structure. On the other hand, it is possible that a polyp may spring from a membrane bathed in the purulent discharge of an ethmoiditis. The same conditions may be observed in connection with aural polypi developing in the course of a purulent otitis media.

Dr. Thrasher narrated the case of a woman who a year after an attack of influenza presented severe pain on the left side of the (slightly swollen) nose, radiating over the side of the face and head, with constant but regular exacerbations. There was an offensive discharge, and the anterior extremity of the left middle turnbinate pressed upon the septum and upon the lower turbinate. On removal of the middle turbinate with the cold snare dead bone was exposed. The adjacent ethmoid cells were curetted and there was no recurrence in four years. A second case was observed in a man, twenty-six years old, who had suffered for two years with neuralgia in the right supra-orbital and infra-orbital regions. The right middle turbinate appeared as a large rounded mass, filling up the middle meatus and pushing out the outer wall of the nose. On attempting to remove the whole mass a large open cavity was crushed into and fragments of necrosed bone were removed.

The general symptoms of the condition are: 1, pain, referred to the orbit or above or below, and sometimes to the ear; 2, discharge, often offensive; 3, nasal obstruction and anosmia, but it must be remembered that the breathing is sometimes unimpeded even in severe disease of the middle turbinate; 4, obstruction of the mouths of all the accessory sinuses; 5, external deformity; 6, various reflex disturbances.

In mild cases alkaline sprays, cocain, scarification, and, if necessary, incision are employed. In older cases the cold snare, trephine, drill, or saw-tooth scissors may be required. Prompt removal of the offending tissue is to be advocated.

DR. THRASHER also related the history of a case of

CONGENITAL OSSEOUS STENOSIS OF THE NARIS.

The patient, a male child, aged eighteen months, was well nourished, but a mouth-breather. There was a muco-purulent discharge from the right nostril. Adenoids in the vault of the pharynx were removed under chloroform. A probe passed through the right nostril struck an obstacle just before reaching the finger in the naso-pharynx. No opening could be found through it; but pressure with a nasal curet easily broke through. It seemed to be a thin web of bone, thicker at the septum, running across and thinning out just opposite the turbinate bone on the lateral wall.

DR. L. W. LANGMAID, of Boston, said that he had seen three cases of congenital nasal occlusion. Such noses are incapacitated for immediate performance of physiologic function after operation. Hence mouth-breathing is likely to continue for a certain length of time.

DR. INGALS remarked that many cases of adenoids presented partial closure of the posterior nares, and in every operation he makes it a point to ascertain the potency of the nares by passing a probe back into the naso-pharynx before the patient emerges from the anesthesia.

DR. JONATHAN WRIGHT, of Brooklyn, read a paper on

CYSTS OF THE NASO PHARYNX AND ORO-PHARYNX AND FIBROMA PAPILLARE OF THE NASAL SEPTUM.

He contended that cysts of the naso-pharynx and sinuses of its mucosa are very rare. The pharyngeal "bursa" is not a normal occurrence. It and the cysts result from the agglutination of the folds and projections of the membrane, as these latter occur in infancy. Hence a partially or completely closed cavity results, from which drops out mucus or which is gradually distended. Transverse section through the folds of the naso-pharyngeal mucosa of a newborn child discloses oblong spaces in the lymphoid or connective tissue, or just at their junction. These spaces, presumably lymph-spaces, are lined by a single layer of endothelial cells, and it is probable that cysts can arise from their gradual dilatation. Dr. Wright related the case of a woman, aged twenty-eight years, who had complained of nasal obstruction for seven years. A soft pedunculated freely movable vascular mass presented in the left nostril in front, and was removed with the cold-wire snare with only moderate hemorrhage. It was attached to the upper part of the cartilaginous septum, about 2 cm. behind the columna. This site coincides with an area subjected to the attrition of the upper end of the triangular cartilage forming the ridge known as the "plica vestibuli." In this case it rubbed against the septum, when the lower edge of the triangular cartilage was rolled out by muscular action in the dilatation of the ala nasi during inspiration. The base was cauterized, and in nine months there had been no recurrence.

DR. NEWCOMB stated that he had recently removed a similar formation with the cold snare, and without hemorrhage. There was still a mass *in situ*, and presumably he had a multilocular condition to deal with.

DR. LANGMAID had recently seen a naso-pharyngeal cyst the attachments of which were such as to forbid the use of the wire snare. It was accordingly removed by avulsion. When recurrence occurs in these cases, it is possible that the cyst-wall has not been thoroughly extirpated.

DR. W. H. DALY, of Pittsburg, opened the discussion upon the

RELATION OF VASOMOTOR DISTURBANCES TO DISEASES OF THE UPPER AIR-TRACT.

He pointed out that the nasal mucosa may be pallid and permit a leakage of serum. His own cases showed cures by intra-nasal operation in 63 per cent. of catarrhal

and hay-fever asthmas, and 40 per cent. of the spasmodic variety. His general conclusions were: 1. Abnormal disturbances of vasomotor origin may be primary or secondary. 2. Both may be coactive and progressive. 3. The surest and quickest relief comes in those cases in which surgical interference finds its proper election.

DR. MULHALL remarked that there is a pallid as well as a turgescent variety of nasal vasomotor disturbances, just as some people get white and others red when angry. The mode of living has much to do with the production of these conditions. Proper diet and exercise will do much to relieve them. Dr. Mulhall advocated daily cold-water frictions, mild galvanism, atropin, gr. $\frac{1}{120}$, on rising, and one-drop doses of liquor potassii arseniitis after meals.

DR. SIMPSON thought that if patients were examined more carefully it would be found in most instances that the cause of disturbances in the upper air-passages lay very near the seat of the disease to be treated, instead of being a so-called "reflex."

DR. J. C. MULHALL, of St. Louis, read a paper entitled

THE CIGARET-HABIT.

He said that the smoker, chewer, and snuff-taker all experience a different kind of satisfaction from their respective habits. The cigaret-smoker soon becomes an inhaler. The smoker of a cigar or pipe rarely inhales. The smoke probably does not enter below the first division of the bronchi, and not the lungs proper. A cigaret either stronger or milder than the one generally used does not give the customary satisfaction to the tracheal and laryngeal mucosa. The effect of inhalation is really a pleasurable excitation of the laryngeal and tracheal filaments of the pneumogastric nerves. The amount of absorption from smoke varies, of course, according to the extent of surface, and it has been estimated that in inhalers this surface is three times as large as in non-inhalers. The frequency and ease with which cigarets can be smoked very properly leads to the designation of the habit as "deadly." Moreover, the small amount and frequency of tobacco-consumption are analogous to the effects of giving a certain amount of drug in divided doses.

The evils of cigaret-smoking are local and constitutional. The latter are identical with those of all forms of tobacco, always nicotinism in greater or less degree. In the young these evils are very great. Cigarets are so cheap that they may be said to teach the use of tobacco. The first cigaret never nauseates, as does the first cigar.

Locally, cigarets may aggravate a previously existing condition, but they do not originate any throat-disease worthy of the name. The most that results is a mild hyperemia, or even a slight catarrh, with the ejection by a single effort of pearly whitish masses. Occasionally a few râles, wholly bronchial, are heard. The murderer Maxwell inhaled forty cigarets daily, and, while he was a total wreck as to his nervous system, he had no laryngeal or tracheal disease, as was determined by postmortem examination.

DR. INGALS took issue as to the harmlessness of tobacco on the throat. He has seen pronounced tracheal cough from its use.

DR. CARL SEILER, of Philadelphia, stated that smoking is harmless if the patient does not spit, and thus keep up an abnormal dryness of the pharynx.

DR. LANGMAID regarded the greatest bad effect of tobacco on the young to be its power of destroying consecutive thought. Pipe-smoking is not so harmless as is generally supposed, owing to the heat of the stem, which is kept up by the relatively large mass of fire in the bowl.

The following papers were read by title:

CYST OF THE MAXILLARY SINUS,

by DR. CHARLES H. KNIGHT, of New York;

PEMPHIGUS OF THE PHARYNX AND LARYNX,

by DR. H. R. BROWN, of Chicago;

COMPENSATORY ARYTENOID MOVEMENT,

by DR. WILLIAM PORTER, of St. Louis;

A STUDY IN DIPHTHERIA,

by DR. S. HARTWELL CHAPMAN, of New Haven.

In executive session the following gentlemen were elected to active Fellowship, their theses being respectively as follows: DR. THOMAS HUBBARD, of Cleveland, "Treatment of Acute Laryngitis;" DR. J. E. H. NICHOLS, of New York, "Intra-nasal Causes of Headache;" DR. J. E. BOYLAN, of Cincinnati, "Herpes Chronica Pharyngitis;" DR. F. E. HOPKINS, of New York, "Edema of the Larynx, with report of a Case."

The election of officers for the ensuing year resulted in the choice of DR. W. H. DALY, of Pittsburg, for President, and DR. H. L. SWAIN, of New Haven, for Secretary. The next meeting will be in Pittsburg in 1896, the exact date to be determined by the Council.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, June 3, 1895.

The President, DR. THOMAS G. MORTON, in the chair.

DR. A. HEWSON exhibited several instruments.

1. A DIVIDED SPRING FOR HEAVY BONE-CUTTING FORCEPS.

The forceps presented has been used in four laminectomies with very great success, the ease with which the spinous processes and the laminæ were cut having been remarkable. The forceps is of the general style of the costatome, and, in addition to the purpose already mentioned, it is useful for cutting off plaster bandages. The blades, are set at an obtuse angle to the handles so as to facilitate cutting the laminæ. The upper cutting-blade is serrated like the teeth of a saw. The lower, which is also a cutting-blade, has at its extremity a horizontal projection, similar to that on the bandage-shears, which is to be inserted beneath the laminæ and serves to keep the blade in position while cutting the bone. The handles are much longer, to give greater leverage. The new point to which attention was directed is the divided spring. All the other instruments of this kind are provided with a single spring, which keeps the blades apart. In this instrument the spring is divided so that it can be turned back when not in use, and when extended we get the full power of the spring to open the blades. It is useful upon both the living and the dead body. It greatly facilitates opening the spinal column for removing the cord, and for this purpose is much better than the spinal saw.

II. PORTABLE LIGATURE-TUBE HOLDER.

This holder resembles a gigantic test-tube holder, made of sheet iron, painted white. It consists of two uprights and three shelves. The uprights are $9\frac{1}{4}$ x $4\frac{5}{8}$ inches, having three hollow blocks, $2\frac{1}{8}$ x $\frac{3}{8}$ x $\frac{3}{8}$ inches, placed on the inside at the base $2\frac{1}{4}$ and $8\frac{1}{4}$ inches therefrom, leaving one inch above the top shelf. The three shelves are $13\frac{3}{16}$ x $14\frac{5}{16}$ inches. The first, or upper shelf, has five holes for ligature-tubes, $1\frac{1}{2}$ inches in diameter. The second, or middle shelf, has the same number of holes, $1\frac{1}{4}$ inches in diameter. The third, or bottom, is without holes. The difference in diameter of these holes gives equilibrium to the tubes when in place. On the under surface of each shelf at the extremity is a block with a projection which fits into the hollow block of the uprights. These blocks are opposite to those on the uprights, so that the projections may be pushed in when the holder is ready for use. The space occupied by the whole when apart is $13\frac{3}{16}$ x $4\frac{5}{16}$ x $1\frac{1}{2}$ inches, and weighs in its present crude form eight pounds.

When in use the corks of the tubes are removed and placed in a proper antiseptic solution and the orifice of each tube is covered with mercuric-chlorid gauze. The assistant removes the ligature as required with a pair of forceps, so that it passes directly from the solution to the hand of the operator without handling. This mode of procedure has been in operation at the Jefferson College Hospital for two years past, and has given great satisfaction. The original thought of this mode of handling ligatures was brought about by having each ligature in a separate tube, but this was found to be a cause of infection, as it was impossible to insure the aseptic condition of a fine glass tube for each ligature; and too much time was consumed in the preparation of such tubes.

III. SET OF ANATOMIC INSTRUMENTS.

This set of anatomic instruments is of interest from a historic standpoint of view, as it contains a syringe for fine injection of lymphatic vessels, used by William Hewson, F.R.S., in 1768, in his preparations. This brass syringe is in a perfect state of preservation, with four gold-pointed nozzles. It has been recently used in preparing fine injections of the lymphatics, as in that exhibited to the Academy about a year ago. The large brass syringe was used by the late Addinell Hewson, in his preparations during his student days, and by means of which, with the various attachments, he prepared subjects for fine dissection. The sternum-dilator gives the greatest width possible for aortic injection (6 x 8 inches). In making tallow-and-soap-injections it has been found that veins injected from the heart will hold one-quarter more material than the arteries injected by the aorta, and still some of the cutaneous veins of the extremities will not be filled owing to their finer valves. In introducing the preservative fluid the hydrostatic method is used, the subjects taking from three to five gallons of fluid. The saw is the ordinary fine carpenter's pattern, with an upright handle about three inches from its extremity on the upper margin. The cutting-edge has been lunated anteriorly, while the posterior or handle extremity is at right angles. This is a modification of the Forbes' saw, the cutting-edge of which is lunated. The object attained by the modification is that it enables the instrument to be used in either sawing the cranial bones or the laminæ, which is not the case with the entirely lunated margin. The forceps just described is superior to the saw for the laminæ, giving greater space and more rapidity of action, besides avoiding all risk of injury to the spinal nerves. The case contains, in addition, spaces for two balls of twine (large and small), Hay's saw, enterotome, brain-knife, blowpipe, hammer, chisel, large incision-knife, student's dissection-case with its accompaniments, and stopcock-pipes of various sizes for immediate introduction into the vessels.

DR. CHARLES W. DULLES made some

REMARKS ON FRACTURES OF THE SKULL.

He called attention to a point in regard to fractures of the skull that he believed does not receive in this country, or anywhere except in Germany and Russia, the attention that it deserves, *i. e.*, the mechanism of indirect fractures. This has much more than a purely scientific interest; it may be an important factor in our application of the art of surgery as well. Reference was made to a paper,[1] read eight years ago, in which was expounded, the theory known as the "bursting-theory," of indirect fractures.

The bursting-theory of indirect fractures of the skull may be invoked to clear up many difficulties of diagnosis in fractures of the skull, and should invariably be invoked before conclusions of a medico-legal character are reached.

Both in the living and in the dead the application of the "bursting-theory" has furnished very instructive suggestions in regard to the diagnosis of accidents to the skull, making them much clearer and the treatment much more satisfactory. An appreciation of the bursting-theory also often clears up the perplexities of cases in which, without detectable fracture of the skull, there is found a rupture of bloodvessels and hemorrhage within the cavity of the skull, either extra-dural or intra-dural.

Briefly stated, the bursting-theory may be outlined as follows: The skull is a hollow case, of a somewhat ellipsoid form, the wall of which is formed of bone, varying in thickness and density in different parts, and of a peculiar conformation, and with peculiar contents and coverings. When such a case is struck, or when it strikes upon a resisting body, it is compressed in a direction in the line of the force and counter-pressure (which latter may depend wholly on *vis inertiæ*). The result of this compression is to shorten the prime diameter, and of necessity to lengthen the transverse diameters. As illustrating this first phase of action, Sir Charles Bell, in the early part of this century, made an experiment (which it is easy to repeat), in which he placed movable balls inside and outside of a hoop and touching it, and found that a blow upon any part of the hoop caused the ball immediately under it and that immediately opposite it to move toward the center of the hoop, while those distant ninety degrees from it moved away from the hoop. If this experiment were to be modified so as to meet the conditions of a hollow sphere instead of a circle, we might place half of a hollow sphere upon a resisting surface, and striking it on the upper pole would

[1] Trans. Coll. of Phys. of Philadelphia, 1886.

find that this pole would approach the resisting surface and the circumference would be elongated and describe a larger circle. In such an experiment, made upon an elastic substance, the compression and elongation would be followed by a corresponding expansion and shortening. The first compression and elongation spoken of are of the chief importance in indirect fractures of the skull, and in them we have (to use a simple illustration) conditions similar to those when an umbrella is raised. In the latter case it is plainly seen what takes place, namely, that, as the pole is brought nearer to the equator, this is elongated and the space between the meridians (the ribs of the umbrella) is increased. This increase being expected and provided for by material which lies in folds between the meridians, this is simply spread out. In a body with no such provision, however, any force that would bring its poles near together, and consequently lengthen its equatorial circumference and separate its meridians, would at once set up a struggle between the force applied and the cohesion of the particles lying along and between the meridians. If the power of cohesion were sufficient, there would be no disruption; if, however, it were not, then there would be a split beginning at some point near the equator, where the strain is most severe, and passing in opposite directions toward the poles. This is what would take place in a perfectly symmetric homogeneous elastic body. What naturally takes place in the skull is shown by observation and experiment to be this, modified by the peculiar structure, formation, contents, and surroundings of the skull.

This is what is known as the "bursting-theory," and its bearing upon practice will be appreciated by those who apply it. It provides the surgeon—not with certainty of diagnosis, but with suggestions of probability, which will increase his chances of making a reliable diagnosis. The inferences from it, which are of a practical nature, as are follows: Force applied to the skull, of sufficient violence and rapidity of action, will produce what is known as a direct fracture—a fracture at a point where the violence was applied. In these cases the rapidity of action is a very important element, as it is a well-known fact in physics that time enables cohesion to resist a disruptive violence, which, if instantaneously applied, would at once overcome cohesion. Force less sudden and less extreme applied to the skull will bring actively into play the elastic properties of the skull, and if violent enough will lead to a fissure at some distance from the point at which the violence was applied, and usually in a line meridional to the point where the force was applied. Study of a large number of accidental and experimental fissures indicates that blows upon the forehead directly in the middle line are likely to produce a fissure of the skull, passing from front to back in or near the middle line, and more frequently at the base of the skull than in the vault. Blows applied to the forehead on one side or the other are likely to produce fissures in a line with the direction of the force, and crossing the skull to the other side. Such fissures occur almost always at the base, and they usually terminate in the middle cerebral fossa, though they sometimes cross the foramen magnum and traverse the cerebellar and posterior cerebral fossæ. Force applied to the middle of the occiput usually produces a fissure passing in the direction of the force around the occiput, laterally or perpendicularly, sometimes separating the lambdoid suture, sometimes splitting the lower part of the occipital bone and going into the foramen magnum, and sometimes crossing the petrous bone, breaking it transversely and passing into the foramen lacerum medius. Such fissures may pass straight down to the foramen magnum and (crossing over) split the body of the sphenoid bone and extend into the ethmoid or frontal bone. (Such fissures furnish typical illustrations of the correctness of the bursting-theory.) Force applied to the side of the head, in almost all cases, produces a fissure passing through the base of the skull in the middle cerebral fossa. Such a fissure sometimes traverses this fossa completely and may pass completely through the base and vault, dividing the skull into two halves. In some cases the fissure passes directly through the coronal suture; in many cases it splits the petrous bone longitudinally. In some cases force applied to the side of the head causes a splitting off of the posterior clinoid processes—an occurrence that is explicable only upon the supposition that the tentorium cerebelli, which is attached here and to the occipital bone, is put upon the stretch when the skull is elongated antero-posteriorly and drags these portions from the body of the sphenoid. Force applied to the side of the head frequently produces fissures passing around the side of the head, through the parietal and squamous bones, and often passing to the basi-sphenoid, but rarely dividing it completely. In some cases force applied directly to the vertex produces a fissure in the long axis of the skull. Such a fissure may be of very great extent and may even divide a skull into two symmetric halves. Longitudinal (antero-posterior) fissures occur more frequently at the base of the skull than at the vault.

An interesting form of violence, applied to the skull, is that due to falls upon the feet, where the momentum of the body is suddenly arrested by the resistance of the earth. In such a case a ring of bone surrounding the condyles may be driven into the skull, or—as observation and experiment show—the process of the sphenoid bearing the posterior clinoid processes may be broken off by the pull of the tentorium cerebelli, when momentum and resistance lessen the diameter from condyles to vertex and lengthen the diameter from occiput to sinciput.

There are fractures that cannot be accounted for by the bursting-theory. There are some fractures in which the force applied is so great and acts in such a manner that the skull is crushed so as to hide any evidence of the play of its elastic properties, the fracture being of a comminuted sort; and there are others in which one segment of the skull seems to be shoved over the other by forces of pressure and counter-pressure which require some study before their mode of operation can be understood. For this reason it is of importance to learn in every case the position which the skull has held in relation to the spinal column or to any body capable of exerting counter-pressure. No less is it important not to overlook the counter-pressure that is caused by the simple *vis inertiæ* of the skull and its contents.

The conviction was expressed that the supreme law governing the production of indirect fractures is that which depends upon the fact that the skull is practically a hollow elastic case approximately oval in shape, and which may be briefly formulated as follows: When a

sufficient force is applied to any curvilinear part of the skull, if this part do not give way immediately, the axis of the skull lying in the same line as that of the applied force is shortened, and all the axes lying in planes at right angles to this line are correspondingly lengthened, with a proportional lengthening of their circumferences and separation of their meridians, so that the direct depressing force is converted into an indirect disruptive force acting at right angles to the direction of the former. The effect is to produce a fissure or fissures which will have a general meridional direction.

The application of this law is subject to certain modifications due to anatomic and architectonic peculiarities of the skull, its coverings and contents, and to certain exceptions due to the amount and velocity of the force applied as well as the coming into play of peculiar counter-forces.

DISCUSSION.

THE PRESIDENT asked if the alteration in the conformation of the skull, the shortening of the axis in the direction of the applied force, and the lengthening of the transverse axes had been accurately determined by measurement.

DR. DULLES replied that the alteration had been carefully measured, and there was an appreciable difference, the amount of which is mentioned in the earlier paper.

DR. HEWSON asked if, in connection with the remarks upon the fractures of the clinoid processes, the fact had been taken into consideration of the difference in the height of the free concave margin and anterior attached extremities to the posterior clinoid processes? Owing to this, the portion of the tentorium open for the passage of the nervous substance is triangular, with curved sides, and this is much higher than its attached anterior extremities to the posterior clinoid processes. The direction of the free margin of the tentorium is pointed upward over the superior vermiform process of the cerebellum, this margin being higher than its anterior attachment. It was also asked if the direction of the traction upon the posterior clinoid processes contributes anything to the fracture? Has any laceration of the margins of this opening been observed?

DR. DULLES said that whether or not the posterior clinoid processes are higher than the arch of the tentorium depends much on the way in which the skull is held. Under ordinary circumstances, when the head is held erect, they are about on the same level.

DR. HEWSON said that the tentorium arches upward.

DR. DULLES added that he had not overlooked this fact in his study of fractures of the skull. Under ordinary circumstances the curve of the tentorium would supply an amount of slack material which would prevent any pull on the clinoid processes. But it must be remembered that the tentorium rests upon the cerebellum and is held tense by the falx cerebri above the cerebellum, and is so attached that the latter occupies a closed, unyielding case. The brain-substance is so largely made up of water that it is almost as incompressible as water [which is practically entirely incompressible], and the cerebellum will hold up the tentorium almost as effectually as if it were made of marble, and so cause a pull at its posterior part to be transmitted to its anterior attachments.

NEWS ITEMS.

The Third International Congress of Physiologists will be held at Berne, from September 9 to 13, 1895. Membership of the Congress shall be open to all professors and teachers of biologic science, belonging to a medical faculty or any other similar scientific body, as well as to all scientific men engaged in biologic research.

The sessions of the Congress shall be devoted to physiologic communications and demonstrations. Further, communications relating to original research in anatomy, general pathology, and pharmacology are acceptable in so far as they present features of general biologic interest.

It is desirable to keep the communications as far as possible demonstrational and experimental in character.

The languages recognized as official at the Congress are English, French, and German.

Each person who makes a communication shall sign the protocol of his own communication.

The length of a communication may not exceed fifteen minutes.

The press shall not be officially admitted to the Congress; each member is free to send private communications to scientific journals.

Professor Kronecker, Director of the Physiological Institute of the University of Berne, has kindly expressed his readiness to afford to members of the Congress all facilities for demonstration and experiment, as well as for the exhibition of scientific apparatus.

In connection with the Congress, an exhibition of physiologic apparatus will be held. Exhibits may be contributed by all members of the Congress, by the directors of physiologic laboratories, and by makers recommended by any member of the Congress, or by the director of a physiologic laboratory. The exhibition of apparatus will open two days before the Congress, and will close two days after the Congress.

Those intending to be present should kindly notify their acceptance, and, if possible, the title of their communications, either to Professor Hugo Kronecker, Berne, or to C. S. Sherrington, General Secretary for the English Language, 27 St. George's Square, S. W. London.

Titles of communications may also be sent to Frederick S. Lee, Secretary of the American Physiological Society, Columbia College, New York City.

Hospitals for Tuberculosis.—At the recent meeting of the American Climatological Association the following preamble and resolution were unanimously adopted:

WHEREAS, Since tuberculosis has been demonstrated to be a communicable disease, it has become doubly desirable that hospitals for the reception of the poor afflicted with this disease should be established,

Resolved, That the American Climatological Association recommend the establishment of such hospitals in every State, not only for the relief of the great suffering attending this disease among the poor, but also as a protection of the community against its spread.

Relative Standing of the Graduates of the Various Medical Colleges, examined by the State Board of Medical Examiners representing the Medical Society of the State of Pennsylvania, June 18–21, 1895:

Medical College from which applicant graduated.	No. examined.	No. failed.	Per ct. of failures	Aver. grade.
University of Pennsylvania . . .	136	1	0.73	86.41
Jefferson Medical College . . .	65	3	4.68	85.28

The Fifth International Congress of Otology will be held at Florence, Italy, from September 23d to 26th. The Committee of Organization includes the following American names: Drs. C. J. Blake and Orne Green, of Boston; A. H. Buck, H. Knapp, and St. John Roosa, of New York; C. H. Burnett and Laurence Turnbull, of Philadelphia.

Dr. Bransford Lewis, of St. Louis, has resigned his position in the Missouri Medical College, and has been elected Professor of Genito-urinary Surgery in the College of Physicians and Surgeons, and Genito-urinary Surgeon to the Baptist Hospital.

For the Report of the Trial of Amick vs. Reeves we have received, additionally, from Drs. John Elfers $1, C. R. Pickering $1, E. Kush $1. P. M. Jones $1, W. Osler $10. Dr. Reeves has received besides from Drs. J. T. Whittaker $5, S. Solis-Cohen $2.50.

ABNORMALITIES IN THE COLOR OF THE HUMAN HAIR.[1]

With a Report of Cases.

BY J. ABBOTT CANTRELL, M.D.,

OF PHILADELPHIA;

PROFESSOR OF DISEASES OF THE SKIN IN THE PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE; DERMATOLOGIST TO THE PHILADELPHIA HOSPITAL AND TO THE SOUTHERN DISPENSARY.

ACCORDING to the literature of the subject, I find that the abnormalities in the color of the human hair are found to be gray or white, blue, green, yellow, red, brown, black, and that peculiar condition in which one hair has segments differing from others of the same hair. I also find that a number of instances have been recorded wherein the change has been periodic, without any known cause, or in which season has seemed to be a predisposing factor; and still others in which the hairs have regained their normal color after several years or more of abnormalism.

The abnormal color may be congenital, as in the many cases of albinism, and, while this condition is more prone to be seen in the negro race, it often occurs in whites. It may be complete, and generally it is the offspring of albinos that show this condition; but an example is mentioned by Hutchinson of an albino child being born to parents who themselves were dark. This is the only case on record that I can find, although Kaposi said, in 1874, that it was a well-known fact. In my search I could find no reference to any case of albinos giving birth to other than albino children. Cases have been recorded wherein this condition has been partial, as in those mentioned by Godlie and Morgan, in which a tuft of white hair was mingled with the normally colored ones, this peculiarity being inherited as late as the fourth generation. Anderson refers to a similar example occurring through the third generation. There are many examples in which this change has occurred in the colored race, as that of the so-called leopard-boy, who was exhibited in museums. A case appeared at my clinic some years back in which a colored woman, thirty years of age, presented a tuft of white hair immediately in the median line of the forehead which had a diameter of two inches or more; the woman also presented a difference in the color of the eyes, one being of a bluish tinge, while the other was brown. This woman was accompanied by her daughter, who had exactly the same condition of the hair as well as of the eyes.

The premature loss of color in the hair is no less an important condition, and whether it is a family predisposition or whether it takes place more or less suddenly, whether it is caused by some derangement of the nervous system or accompanying some depressing or grave disease, it is nevertheless abnormal enough to claim our attention.

I have made no attempt to collect those cases in which family predisposition has been a possible cause, as all are aware that this takes place, and I feel that it would be a waste of time to give more than a passing notice to that condition.

In many cases this condition of graying or whitening of the hair has been more or less sudden, and the cause has been one of the conditions enumerated.

Of the many cases in which the change occurred in a few hours or a few days, I include those of many writers. Mention may be made of those in which the change took place in a very few moments, as the persons were either brought out to execution or were awaiting the hangman's noose or the knife of the guillotine. Darwin, quoted by Walter Smith, mentions a man whose hair while being brought out for execution changed color before the eyes of the spectators. Laycock refers to a Sepoy who became gray in one-half hour. Parry states that a prisoner became white-haired within fifteen minutes while confined in the guard-house. Wilson refers to a young lady who was awaiting her affianced to come home to conclude his marriage ceremony, and who suffered the same effect on hearing of his sudden death. Smilie speaks of another case, that of a young man awakening and finding a grizzly bear lapping the blood which was flowing from a wounded arm. Dewees found gray hair on the forepart of a woman's head during her accouchement, which returned to the natural color in four or five days. Boyle met with this sudden change in a young man who was seized by the guards and was, as he thought, to be put to death. Miner witnessed it in a young boy who had learned of his mother's death. Sir John Forbes, who had gray hair, suddenly became white, which condition remained for a year, and at the end of which time it again returned to the gray.

[1] Read at the meeting of the Philadelphia County Medical Society, April 10, 1895.

Other cases are mentioned by Schenk, Hahnemann, Pechlin, Birsch-Hirschfeld, Nicholaus Florentinus, Borelli, Callius Rhodiginius, Eulenberg, Seligmueller, Marcellus Donatus, Fabricius Hildanus, Camerarius, Scalinger, and others.

There are other cases in which the change was less sudden, such as that of Brown-Séquard, who noticed the change day by day in his own person; of Sir Thomas Moore, the Chancellor of Henry VIII; of Henry of Navarre, who changed in twenty-four hours; the Monk Ubipertus, who had to become gray in one night to obtain a bishop's miter; Louis of Bavaria, who had condemned his wife to death; the well-known Perat, the wife of Laclere, who had to give testimony before the Peers in the case of Louvel; Marie Antoinette, but whom Charcot proved had gray hair before the death of her husband; the case of Smyth, in which a light-haired young man became gray in some places and jet-black in others; those of Landois and Pye-Smith, in which the change was noted after a debauch or delirium tremens; Ludwig Sforza, who had fallen into the bad graces of Louis XII; a man who turned gray in one night after military service in very cold weather, as referred to by Hardy; Smythe's patients, who turned gray in some parts while others became black, the skin also changing to a bronze; that of Banks, in which a young woman showed the condition on the eyelashes; Smilie's case of a young man, who had staked his all on the fortunes of a card, and who winning found on the next morning that his hair had become gray; Fowler's case of a girl who was chlorotic and who had a gray spot, two inches square, on the occipital region; the friend of Ferguson, who changed after business losses; a young girl of thirteen, who, according to Howe, awoke one morning and found a spot one-half inch in breadth on one side of her head, the other showing the change soon after, and the whole head undergoing the change in seven years; this writer also refers to a girl of eight years who had light hair on one side and dark-brown on the other; Anderson saw a case affecting the upper eyelid, in which this part, with the left whisker, was also white and of some years' duration; Thornton gives the notes of the case of a young lady in whom the eyebrow and lash became white within a week after a sudden fright; Faldenheim speaks of a change beginning at the age of twenty and being complete at thirty-three. Cases occurring in four or five days are also recorded by Richter, Bichat, and Moleschott.

Villerme records that in a girl of thirteen the lost hair was replaced by a woolly growth on part of the head and by brown hair on the other, which after a time faded into gray, some of which fell out and left a sad condition of affairs. Brandis has seen one side of the beard white, while the other retained its natural color. Of the many cases in which disease has been a predisposing factor I include that of Crocker, in which the eyelashes became white consequent to a sympathetic ophthalmitis, after removal of the opposite eye; and still other instances of this are spoken of by Nettleship, Hutchinson, Jacobson, and Schenkl. Cases following neuralgia are mentioned by Wilson and Paget, and in the latter there would be a return to the natural color in four or five days, Berger's being witnessed after a hemiplegia on the right side of the head and face; Murray met with it after the removal of a fibroid tumor of the uterus, and in this case it occurred after a severe neuralgia during the night, being confined to the internal half of one eyebrow and the corresponding eyelash. It has also been noted as occurring with epilepsy by Marselli and Beigel; with locomotor ataxia by Bulkley, Debove, and Bartholomy; coincident with cerebral tumor by Bourneville and Poirier; following typhus by Joannet; and in malignant fever in a case of Compagne, the hair was noticed to turn completely gray by the sixth day, but on the seventh it commenced to turn dark, and on the fourteenth it had become its original black color. Raymond observed this condition in a woman of thirty-eight, who parted with her son and who afterward lost money; during an attack of neuralgia she found upon the upper part of the head that the hair had turned red, while the remainder was completely white. Lorry says that graying of one side sometimes follows severe toothache; Wallenberg refers to a child having scarlatina, in whom the hair and nails fell out, and were replaced by a milky-white skin and albinotic hair; Naylor also speaks of a similar cause in his case; Ludwig has known the eyelashes to change color after smallpox.

Following this condition we have another in which we are confronted with the so-called ringed hairs, and several cases of this very interesting abnormality are recorded by Wilson, of a boy of seven years in whom the normal or brown segments were one-fiftieth of an inch long, and the white and abnormal segments were about half this length. To be mentioned also is Lesser's case of a child of four-and-a-half years, who was born without any hair, excepting the eyebrows, which were normal, and soon after the scalp presented the appearance of goose-flesh. The hair began to grow by the second year, the color being brown; the longer hairs were normal, while the short hairs were generally ringed. In this case there was also trichorrexis nodosa. Karsch has referred to a case in which the rings were not of uniform size; Crocker speaks of the moustache of a gentleman, aged thirty-nine years, which was also associated with trichorrexis nodosa; Richelot mentioned a chlorotic girl, in whom the hair became gray for two or three inches at its root, the parts beyond being unchanged. The chlorosis was cured by iron, and the hair-pigment was again

secreted, so that after a time she had brown hair at the roots and ends, the center still remaining white. Smith, Spies, Landois, G. Simon, and Thomson also have seen this condition; Unna speaks of a case of white nails, in which there were also ringed hairs.

In the following illustrative case the patient was a man of forty-seven years of age, who was brought, about the middle of the year 1889, to my clinic by Dr. John A. Fell, of Doylestown, Pa. I obtained the following history: His paternal grandparents lived to be eighty-two and eighty-four years of age, respectively, and his father was eighty years of age at the time of his death. He had two paternal uncles, one dying at the age of sixty-five of pneumonia, and the other of dissipation; there were two paternal aunts, one of whom died at the age of seventy, from a fall down stairs, and the other at the age of sixty-five years. All had good heavy hair, which was of a dark-brown color, the man's father having very few gray hairs at the time of his death. Of the maternal grandparents, his grandmother lived to be quite aged; his mother lives still at the age of eighty years. Of three aunts, one died before the birth of the patient, and consequently he was not aware of her state of health; another died during parturition at the age of forty years, and the remaining one in old age. The uncles were quite aged at the time of their death, being seventy-eight and sixty-five, respectively. The members of this branch of the family were of a sandy complexion, their hair turning gray or white at an early age in every instance. The patient had three brothers living at the ages of fifty-six, forty-nine, and forty-two, respectively, and one sister at the age of fifty-five years. In all of these the hair had not undergone much change, although in the eldest there was a slight tendency to become gray.

The members of both families, from the grandparents down to the present generation, had always enjoyed the best of health, with the exception of the patient's mother, who had always been a sufferer from temporal neuralgia.

The patient was born in Pennsylvania, October 22, 1842, and was, therefore, forty-seven years of age. He had two sons living at the ages of twenty and sixteen, respectively, there having been a stillborn daughter between the males. His habits have always been steady; he was never a drinker, or otherwise "fast;" he had never suffered from gonorrhea or syphilitic infection. At the age of four years he had typhoid fever.

During the War of the Rebellion he was wounded on September 17, 1862, suffering a compound comminuted fracture of the fibula, caused by a Minie-ball. He was confined in a hospital for five months. He suffered from iritis in both eyes, the marks of the cupping still being visible in both temporal regions. Since the war he has been troubled with "army diarrhea." He was a moderate smoker.

The trouble for which he sought advice began in November, 1888. He complained of severe pains in his head (no particular portion), from which he was unable to sleep except in short naps; he could not describe these pains accurately. During the day he was almost unable to keep a hat on his head, although it was of light weight, because it felt as if a stone.

These symptoms continued through the winter and summer until July, 1889, about the middle of the month, when, on going to the mirror one morning to comb his hair, he found a white streak on the right side of his moustache. The following day this side of his moustache was perfectly white, the left side showing no tendency to change. Within the next ten days the hair, formerly dark brown, changed color in its entirety, and gradually fell out until there remained only about one-third of the normal amount. At this time he gave me two pictures, which illustrate the appearance of the man just before and just after the changes occurred.

He says that when he goes to bed he is sleepy, but that when he reaches the bed he lies awake for several hours.

On January 5, 1895, I found that there was no change in the color of the hair, except as regards the portion in the occipital region, where the new hair is of the normal color before this change took place. The color of the other portion remains as white as stated in the previous notes. The man told me that he had just about enough hair upon his face to make it necessary to shave once a week.

In bringing this case to the attention of the Society I wish to show plainly that this sudden blanching of the hair does occur. I cannot understand why so many of our medical teachers state positively, even to this day, that it is impossible. Kaposi said in 1874 that there was no such thing as sudden blanching of the hair, and that if the cases had been examined previously to this so-called change it would have been seen that the condition was gradually taking place—that is, that the pigment was losing its power of giving normal color to the hairs. This writer was not alone in this assertion, as such men as Haller, Barensprung, Reisner, and Hebra were counted in the list. I therefore feel great trepidation in reviving the subject at this time.

The condition of sudden change must certainly have been known, for if we refer to the words of Lord Byron they are certainly conclusive:

> "My hair is gray, but not with years;
> Nor grew it white
> In a single night,
> As men's have grown from sudden fears."
> (*Prisoner of Chillon.*)

The question remains, Why in one instance a person will have brown hair, or red hair, and in still another it will be black? This can only be determined by the number and size of the air-bubbles that are contained within the hair. In the black hairs we have the air-bubbles in minute quantity, while in those of brown hairs we have them in some slight increase, and they are found in larger quantities still in the red hairs. Taking these points into consideration and examining the refractive power of the hairs in this connection, we can readily understand how one person will have color differing from another. And the same explanation may be applied to this sudden loss of color in its structure. We have, perhaps, through nervous shock or some unknown cause, the collection of air-bubbles in large quantities throughout the entire hairy system, and, as the refractive power of the hair becomes changed, we are confronted with this apparent loss of color.

Pfaff has stated that the pigment is not diminished until advanced age, but I am of the opinion that, except in albinos, the hair is never devoid of this coloring-matter. If the theory is correct that we have a loss of pigment in advanced age, how can we account for the return of normal color of the hair in very old persons? I do not think that reformation of pigment will ever take place, the color not being transmissible, but is due to the amount of air-bubbles contained within the hair.

If the statement be true that air-bubbles are the direct cause of this condition, it would appear that the cases recorded by Prentiss, in which one of the patients was treated with jaborandi and the other by pilocarpin for some intercurrent malady, and in whom the normal color of the hair returned, would tend to prove it; and the experiments of Pohlman with pilocarpin, in which he obtained the return of color in certain cases, and yet was unable to secure it in an albino rabbit, would add testimony in this direction rather than disprove it.

BLUE HAIR.—Many cases are recorded in which the change has been to a blue in those who are workers in cobalt-mines or who are employed in the manufacture of indigo; thus Borellus records the case of a man who had worked in the manufacture of indigo for twenty-five years, and whose hair had been blue for at least twenty years. In the case of Beigel, the blue color did not penetrate into the substance of the hair, but particles of indigo were deposited in an irregular manner upon the cuticle of the hair.

GREEN HAIR.—Green hair has been witnessed in those who are employed in copper-mines, as in the case of Petri, of a man of seventy-eight years, in whom the hair of the scalp was green, but in whom the hair became its natural color after washing in solution of caustic ammonia. Billi refers to a man with ringworm of the scalp, who was treated with corrosive sublimate and an ointment of yellow mercuric oxid, and in whom the hair became green. Another case is recorded by Orsi, of a railroad-workman who became suddenly green-haired, the green hairs being mixed with the gray; washing with ether, alcohol, or a dilute solution of potash did not affect it, but the hair on being cut grew out again gray. Clapton met with cases of green hair in copper-workers, and Wiltshire in those who were pin-makers. Joseph Frank also observed it. Rommel met a man of thirty years thus affected, but who had never worked in a mine. Borellus records the case of a young man who had green hair and green perspiration. Blue hair is also seen in those who work in brass. Leonard, Bouchardat, and Posner believe that the colors, both blue and green, are only superficial, and can be easily rubbed off; but Elbe, who has made a comprehensive study of this condition, states that this discoloration is not alone confined to the superficial part of the hair, but is intimately connected with its entire substance and cannot be rubbed off. The recorded cases disprove the latter assertion of Elbe.

YELLOW HAIR.—Smyly records the case of an infant of four months whose hair changed from its usual mouse-color to that of a reddish-yellow. The right eyebrow and the skin of these parts, as well as that of the right hand, were icteric; the pillow also was saturated with a reddish-yellow perspiration. Walter Smith tells of a boy in whom the lobe of each ear was of a sulphur-yellow, the downy hairs being also a bright yellow, while the hair of the head was brown. Many cases have been seen in which chrysarobin and chlorin gas have produced this same condition. Hydrogen dioxid, as is well known, is used to bleach the hair.

RED HAIR.—McMurray mentions a man having a hemihyperidrosis of neurotic origin and herpes zoster of the corresponding side, in which the hair of the affected side was of a light red, while that of the other was dark. Squire referred to a deaf-and-dumb boy of sixteen who had dark-brown hair in some places and auburn in others, and which to some extent resembled a tortoise-shell cat. Isoard describes a young lady, who was deaf and dumb from birth, and who every time she had a certain fever the hair, which was of a pleasing blond, became a dusky red; but that so soon as the febrile symptoms diminished the hair became natural. Alibert records an almost similar example; he also refers to a case in which after a severe illness a head of brown hair became one of bright red. Mention may also be made of the offspring of parents who are dark and who show a tendency to reddish hair. Congenital redness has been witnessed in members of the colored race. Leonard speaks of a young man who had brown hair, and which afterward became a positive red after a few years' residence in the hot climate of Sumatra.

BROWN HAIR.—Wilson cites an instance of a man whose white hair turned to a brown and back to gray again before his death, at the age of one-hundred-and-fourteen years. Belcher refers to a woman of ninety-five, who had been insane for fifty years, and who at her death had brown hair, there being not a single gray hair on her head.

BLACK HAIR.—Pyrogallic acid will make the hair black. Wilson records an example of the change to black in a woman of ninety-five, whose gray hair turned to black, and which became gray again before her death, at one-hundred-and-five years. The cases recorded by Prentiss are indeed unique: the one in which a woman of seventy-two was given pilocarpin, and the other of a woman of twenty-five who had taken jaborandi, in both of whom the hair became black. Sykes referred to a man of eighty-one, who had white hair which in

a few years became black, and Bruley to a woman of sixty years, who had naturally white and transparent hair, which became jet-black four days before her death. Albert alludes to a person in whom the hair, from having been previously brown, became deeply black. Copeland remarks that in a number of instances gray hair has become black. Beigel refers to this change taking place after typhus fever; this was witnessed in a woman who had blond hair, which was replaced by coal-black hair.

Periodic Changes.—Warner records the case of a gentleman whose hair turned from black to white and back again three times in thirty years; the change from black to white was always rapid, while that in the other direction was slow and took some five years for completion. There would be a pause of some years when the color was normal, and then it would become white again. Reinhard gives the notes of a case wherein, in an idiot, the change was periodic, being from a reddish to a blond yellow. Rauber records a case of this change in an epileptic. Wilson saw it gray in winter and natural in color in summer.

Return of Color.—Isdell refers to a man of sixty-two, with gray hair, and when eighty-three it was of its former normal color. Allanson Abbe speaks of a case returning from gray to quite dark, and even black in places, mingled with gray hair. Graves records many examples; one was blistered, and the hair came in black, and remained so. Another was bald on the vertex, forehead, and temples; this was blistered, and a growth of hair occurred in a ring. There was also a girl who had several bald spots remaining after a tinea; in this case common gas-water was used, and the hair regained its natural color. Still another was that of an army-officer who had been in the East. Sir John Sinclair mentions a Scotchman dying at the age of one-hundred-and-ten, in whom the hair regained its normal color. Joannet speaks of several instances, one of which was in a man who had been campaigning in the East, and in whom, upon remaining home for a year, the normal color of the hair returned; another patient took a sea-voyage for a year, with the same result. Hoffman records the case of a gentleman who was an incessant user of tobacco, and whose hair became gray; upon relinquishing the tobacco the hair again became black. W. O'Neil refers to a man who was gray and bald; three-and-one-half years after hemiplegia, and at the age of sixty-two, he noticed that dark hair was growing on the bald spots, and the gray hairs fell out and gave place to dark-brown hair.

I recall the case of a friend of about sixty-three years of age, whom I have known to be gray for at least fifteen years, and during the past year or two the normal black color of the hair is showing itself in the new-formed hairs.

Miscellaneous.—Hauptmann refers to a case of a body which had been exhumed more than twenty years after burial, in which the hairs appeared red, whereas the hairs of the individual at the burial had been dark brown. Leonard speaks of a case in which, after death, a head of red hair changed in the course of a few hours to blond, and within thirty hours to gray.

Oesterlin has recorded a case wherein the hairs were more intensely pigmented toward their roots.

If any reported cases are not included in this list, I beg indulgence, owing to my inability to obtain data.

THE MENTAL STATE AS CONDUCIVE TO ORGANIC DISEASE.[1]

BY GEORGE S. BROWN, M.D.,
OF BIRMINGHAM, ALA.

THAT we are at present in the dawn of the age of preventive medicine is accepted by all thinking medical men; hence, the scientific facts sustaining this conviction need no elaboration and but brief mention in a paper of this kind. We recognize that as the accumulation of histologic and pathologic facts has gone on, the medical mind has grown more and more modest in its claims as to the curability of disease. This accumulation of facts has shown, first, that many diseases, from their very nature, are incurable, and at last the old egotism of ignorance entirely gives way when it is seen that all living organisms possess within themselves an inherent vital force, capable, to a large extent, of stamping out and keeping out the causes of disease. With the possession of this knowledge naturally comes the effort to conserve and further the action of this vital force by the development of these means, which are comprehended in the term *preventive medicine.*

While we have learned that death lurks not only in the cup, but in the bowl, the dish, and the milk-can, in the miasma of the night-air and the dust of the busy street, we have also learned that so long as the general health of the human body is maintained, its inherent vital force, through the agency of the phagocytes, is able, for the most part, to resist successfully the invasion of the germs of disease. This inherent vital force, this essence, which is the measure of the desire and ability to live, is doubtless the resulting strength and vigor of the combined sperm-cell and germ-cell at the time of conception, conserved, added to, or wasted, as it is variously affected by the million factors that influence its existence from the time of conception to old age. Every individual possesses it in a different degree, and its variations range all the way from the weaklings that die *in utero* or live an hour, week, or month after birth, to those high examples of physical and mental strength that carry on the work of the world.

The utility of this vital force may be impaired in a variety of ways. In the order of their importance they may be divided thus: First, ignorance of the mental and physical laws of right living. Second, mental shock and strain, and physical accident or exposure, which are unavoidable. For instance, a man living in perfect health in a malarial region breaks his leg. The lowered resistance of his vital force is overcome by the malarial germ, and he develops malarial fever. Mental shock may so depress the vital force as to invite the germs of disease and cause the body to fall an easy victim, or, failing that, may, by its impression on the nervous system, so disorder the bodily functions as to cause in time organic changes.

In the first class of the causes of lowered vital force (those due to ignorance of the moral laws) we need not dwell upon the fact of thousands falling victims yearly owing to the ignorance of themselves and others regarding the laws of physical sanitation and hygiene, but it is to the mental state and the position it occupies in the causation of disease through ignorance of the laws of right living that I wish to invite attention more specifically.

The human mind or brain-function probably never rests entirely, but it must have its equivalent relaxation in a healthful variety of subject, pleasurable change. The business-man, when prosperous, has the excitement of his affairs and his hours of ease and pleasure at his fireside. His drudging clerk, having no family ties, and possessing no artistic or social tastes of the higher order, must resort to cards, billiards, or worse, with others of his kind, while the ignorant negro laborer is limited for mental relaxation to the banjo, the dance, and the crap game, whisky, and the razor.

This mental relaxation, however obtained or whatever the form it takes, is absolutely essential to the healthy performance of the bodily functions. Conversely, high mental tension on any subject, continuing long enough, will cause disordered function, which will in time surely be followed by organic change. The business or professional man laboring under financial stress or overwork is a good example of physical breakdown from mental strain, but the sub-class of cases that I wish to speak of more particularly includes women who are born with, or through long years have slowly acquired, the worrying or fretting habit. This usually begins in childhood. Under the false but popular protection-system of training, egotism and selfishness are encouraged at the expense of self-reliance and self-restraint. I beg indulgence while I report two ideal cases that I have personally encountered, and which will, perhaps, better illustrate my meaning:

A woman, aged thirty-two years, married fourteen years, with one delicate child, a boy of thirteen years,

[1] Read before the Alabama State Medical Association, at Mobile, April 17, 1895.

had always, as a child, girl, and young lady, been regarded as delicate, although she had never had any serious illness. Through childhood she had been indulged in every desire and protected from every irritation by an overfond and self-indulgent mother, and had never learned the meaning of self-restraint. As she grew up, her wants became harder, and finally impossible, to supply, and then the little irritations and deprivations began to cause fret, worry, and general mental suffering. Since her earliest recollection everything in the household had constantly bent to her wishes, and her mind had unconsciously taken the attitude that everything in the world should be made to do the same. Her egotism was developed; her view was distorted by this artificial breeding, until, like primitive man, she thought the universe was made for her. When she came in contact with the world, and life became more complex, the ordinary little irritations, against which she had been protected so unwisely, pressed so thick and fast that husband and mother were unable to shield her entirely, and her mind became gradually fixed in a fret upon her woes, the least of which was more important to her than the real troubles of other people.

This woman's husband was a physician, with a good income, but spending it all in his hopeless endeavor to supply her ever-increasing demands. For five years she was an almost helpless invalid from nervous disorder, with its inevitable train of headache, loss of appetite, sleepless nights, constipation, and indigestion. It should be remembered that all her life she had had all the creature-comforts, had been protected from every extreme of heat and of cold, her stomach had never been called on to digest plain food, and, as a consequence, for ten years she had been under the high mental tension of worrying about the thousand little disturbances of muscles, nerves, and digestion that inevitably follow a habit of little physical and mental exercise, fresh air, and refreshing sleep. After five years of almost complete invalidism her husband suddenly died. She was left sick abed, with a delicate child, an invalid mother, and without a dollar in the world.

What follows proves conclusively that this woman's sum of unhappiness was due solely to her mother's mistaken notion of kindness in never allowing her daughter to learn the necessary lesson of self-reliance, and having taught her instead to be dependent, selfish, and miserable. The mother thought she was doing the best, but she really was engaged in a most vicious and immoral form of self-indulgence; she was pleasing herself, but wrecking her daughter's future health and happiness. In spite of this life of selfishness, this daughter had many friends, was attractive, educated, and highly accomplished in music, painting, and needlework, all pursuits for which she had a natural talent, and which really, no doubt, saved her life.

When her husband died, and stern necessity stared her in the face, she had a hard struggle with her pride, and no doubt suffered a great deal mentally and physically; but whatever the effort cost her she made it, and when I saw her a year later she was keeping boarders, teaching music and painting, and making a good living for the three. Several years after that she was strong and well, had gained thirty or forty pounds, and did not have time to be sick.

This was a case of cultivated invalidism pure and simple, and, if the early conditions had been maintained for a while longer, some organic trouble would undoubtedly have followed—tuberculosis, general nervous exhaustion, or what not.

An ancient Eastern sage once said: "In the course of my long life I have often noticed that men were more like the times they lived in than they were like their fathers," meaning thereby that hereditary tendencies are overwhelmed by the influence of environment or training, when the two happen to work in opposite directions. And so in the case I have just reported. Naturally the woman, that is, her mental and physical heredity, offered the poorest possible material out of which to make an invalid. She was bright, forceful, and intelligent, with every inherent quality to make an energetic, useful member of society, which she finally became by accidentally escaping the usual final consequences of her early training.

I must beg further indulgence while I relate briefly another somewhat similar case, but in which the natural qualities were more favorable to the success of similar vicious early training:

This case also was in a woman, aged twenty-six years, married five years, with no children. The same protective system had been carried out, first by the mother and then by the husband, until all interest in everything but her own petty ills and irritations had been blotted out. At the time I first saw her she had the appearance of robust physical health, but was in a never-ending fret about her husband, her household cares, and the thousand functional disturbances of nerves, muscles, and digestion which constantly attend, as both cause and effect, such mental states as hers; a never-ending list of wants; reproaches for all, in place of thanks and kindly feeling; the interciliary ridges denoting extreme anxiety, high mental tension being never absent. This selfishness and total absence of all self-restraint and self-reliance were her masters, and although no physical disaster had yet been wrought, the result was inevitable.

Physical examination revealed no organic disorder, except a small cyst of the left ovary, which caused no inconvenience other than mental. This state of worry, of high mental tension, however, with its attendant train of bad physical habits, no exercise, no fresh air, no refreshing sleep, indigestion, headache, and constipation, and last, and most important of all, no healthful mental change, her mind on one eternal strain about herself, did the work, and five years later she died a physical and mental wreck. Seeing her again in consultation after this lapse of five years, I could

recognize mental symptoms, such as fretting about trifles, which at first would have been amusing, except for the grave tendency, now grown most pitiable in the intensity of the mental anguish they caused. She had no waking moment for weeks prior to her death that was not filled with the most acute mental and physical suffering. Self-pity and most pathetic charges of injustice and neglect, which she felt to be just, she showered on all about her. These made up her mental agony, and the long-starved-out and abused and exhausted nervous system, crying out as physical pain in every final nerve-distribution, was none the less real. She died with a frown of reproach for all who had loved her and cared for her, and the cause of her general exhaustion, I am convinced, was primarily mental.

The post-mortem examination showed beginning tuberculosis in both lungs and slightly advanced interstitial nephritis. The cyst of the ovary had grown little or not at all; there was no organic change sufficient to cause death, which was due simply to an exaggeration of the mental symptoms present five years, or ten years, or twenty years before, to a point at which the exhausted brain and nervous system could no longer furnish life to the tissues.

These two women had the same vicious early training, and but for an accident in the environment of the former the results would have been the same. The first case was not naturally so bad as the second, because the woman had natural tastes that asserted themselves, and, combined with her maternal affections, took her out of her own thoughts for hours together, thus relaxing the nervous tension, smoothing out the brow, and giving the mind an occasional much-needed rest. It would only have taken a little more time, however, to balance these advantages, and she would have gone the same road as the second. The second woman had no inherent healthy force, no tastes, no talents, although pretending to all; no attractive qualities, and, consequently, no friends, and no affection for anyone but herself. Her mental tension never relaxed, except when overcome by sleep, and of that she had little; consequently there was nothing to obstruct the rapid progress toward nervous ruin.

To my mind these cases tend inevitably in one of three ways: either some acute organic disease steps in and ends the struggle; or this goes on unobstructed to the end, as in the second case; or something occurs that brings about a radical change of habit that effects a cure, as in the first case. Case I could have been cured at any time by a little patient, judicious teaching and intelligent help. Her case was due solely to ignorance on the part of her husband and mother. Case II, with a bad heredity and no redeeming qualities, would have been a harder case to manage; would have required, no doubt, a wise attendant and adviser from her natal hour.

In the management of these cases the intelligent physician can do much, if he will leave his saddle-bags at home, and study the mental condition closely, and rely on his ability as an educator. The "Weir Mitchell" rest-cure is successful in many of the milder cases. It puts away all medicine, and excludes all garrulous friends and over-anxious mothers; but, combined with this, after the patient's confidence has been gained, she should, I believe, be made to understand the mental source of her trouble. She must understand that not only is her co-operation necessary, but that the entire burden and responsibility of the cure are on her; that no miracle can be wrought for her; that there is no royal road to her cure; that her condition is the result of long training and self-indulgence in bad mental habits, and that only by long and patient work in the opposite direction can she be benefitted; that the mistakes and evils of her youthful training cannot be wiped out by a pill or a prayer devised by someone else, but that she herself must long and patiently atone. Those cases can be cured that, like the first case I have reported, have some good left to appeal to—if that something good is appealed to, and the conditions honestly explained, to the end of gaining the patient's confidence and enlisting her co-operation; maintaining the strictest of discipline over her, or rather helping her to do so herself, and showing a most honest sympathy and concern for her welfare, and finally throwing the entire responsibility for the success of the treatment on her. On the other hand, if she has not any stronger desire than amplifying her symptoms in order to revive the waning sympathy of long-suffering friends or to stagger the new doctor with the importance of her case, if she has no reason, tastes, or aspirations left to appeal to, or if she is over fifty years of age, and "sot in her ways," she and her friends will get more peace and happiness from a hypodermic syringe and a bottle of Magendie's solution than from anything else. Cases of this kind, which cannot be dealt with honestly, whose confidence cannot be gained nor co-operation enlisted; in short, those who have little reason and no will-power left, receive but temporary benefit from bread-pills, hypnotism, hoodooism, charms, fetishes, and prayers. Such treatment, in fact, has made these cases what they are.

The two cases I have detailed are typical of the conditions I wished to illustrate, but, like all pure types, are seldom met with. By far the most common form of this acquired or cultivated state with which we have to deal is a variable and ever-varying combination of the two. In brief, it is a state of high mental tension, mental overwork, brought about by a selfish, worrying habit; worse at one time, better at another, as it is influenced by the thousand healthful and unhealthful factors of en-

vironment, but, on the whole, gradually growing worse as the years of youthful frivolity, change, and excitement are replaced by the more monotonous period of middle life. This state persisting, with its accompanying indoor existence, poor air, poor exercise and sleep, dyspepsia, headache, constipation, and no mental relief, the rule is constant; the weakest point gives way to organic disease, or the patient succumbs to pure nervous exhaustion. Again, a monotonous home-life is often responsible for conditions that have in turn been charged to perversity of the liver, uterus, or ovaries. Housewives who suffer from the persistent waywardness of husbands and children, from poverty, confinement, and hard work, with no hope of relief or pleasurable mental change, in ten, fifteen, or twenty years go the way of nervous wrecks, and many wonder why.

These cases are peculiar to women, not because they have ovaries, but because they are so often the delicate hot-house pets of mothers or the unconsidered and unpitied slaves of men. In one case the girl is often completely under the vicious influence of an indulgent and ignorant mother. Her brothers are never beyond a certain age. Neglect a boy's training in self-reliance and develop his egotism to the utmost, and one game of marbles or ball, perhaps, will knock it all out of him. The boy, sooner or later, always has companions who estimate him at his real value, and force him to accept it. They teach him self-reliance as well as self-restraint; they inure him to personal irritation; he sees the world as it is, and early learns that biologic principle that the individual must mold himself to his surroundings.

The girl, brought up under the protection-system, thinks the surroundings can be cut to fit the individual, and working, or rather fretting, under this hypothesis, she grows up unhappy and unhealthy, and with her ovaries threatened by every new doctor she calls. As I have mentioned, this state of high mental tension is often acquired by business-men who have allowed their affairs to grow beyond their strength to handle. Such men, ignorant of or indifferent to the laws of mental hygiene, can, by ignoring the loud clamors for rest for the weary brain, bring about that state of low physical resistance so inviting to infectious or organic disease. The physician's duty in all these cases is almost entirely educational. Such cases in men are easily treated, the condition being obviously a late acquirement. A few months of mental rest will effect a cure.

To an unfortunate woman, whose state is the result of early training, worry is more nearly natural, and to attempt to cure would be to attempt to bring about an actual revolution in her character, and those only can be cured who have some reason and understanding left to appeal to. Let such a woman be told that she has nervous prostration, but let it be explained to her what is meant by that; let her be shown its cause, and be impressed with all the sympathetic eloquence at the physician's command that there is no royal road to her cure; that her improvement will be speedy or slow in proportion as she recognizes her condition; that her physician and attendants can only remind, encourage, and direct, but not cure. She must be warned that this fixed habit, the result of years of bad mental hygiene, can be changed only after long and patient work in developing and reviving the latent and atrophied forces that still remain. Cases that have passed a point where reason, will, and understanding have been all but annihilated may eke out a tolerable existence with anodynes in a continual warfare with the weaknesses that have flourished too long.

To benefit these cases in the line I have indicated there is obviously necessary a state of confidence in the physician, and a faith in the wisdom of his view of her condition. This is difficult of attainment at all times, and after the patient has reached a certain age, or her condition a certain degree, it passes all possibility. Such cases there are, and we have all seen them, who, inheriting this tendency to worry, this lack of will-power and self-reliance and reason, and having been subjected to the ignorant and vicious protection-system of early training, followed by a procession of female sympathizers to encourage every little selfishness and physical and mental ill, and accompanied by medical treatment as comprehensive as it is vague, ranging all the way from bread-pills and asafetida to ovariectomy, have at last reached a point where they have not one force left with which to cope with the tenderest possible conditions of life. The drawn mouth, the emaciation, the quick, nervous eye, the interciliary ridges and furrows, together with the never-ending list of complaints, will recall cases that have fallen victims to infectious or organic disease, or have faded away as simply unfit to survive.

The prophylactic measures that the foregoing ideas suggest obviously comprehend certain advice to the mother of each newborn babe that opens a field too broad for me to enter and a responsibility too great for me to assume.

To Prevent Thirst after Celiotomy HUMISTON (*American Journal of Obstetrics and Diseases of Women and Children*, July, 1895, p. 89) has the patient drink for three days previous to the operation a pint of hot water an hour before each meal and also on retiring, the last pint to be taken three hours before the time set for operating. In this way is restored to the stomach the large amount of fluid lost by the free catharsis. This method has been followed in twelve cases, the patients presenting a moist tongue, active renal function, and freedom from thirst.

CLINICAL MEMORANDA.

THREE CASES OF CHRONIC ABSCESS OF THE BRAIN.

BY J. T. ESKRIDGE, M.D.,
OF DENVER, COL.,
PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF COLORADO; NEUROLOGIST TO THE ARAPAHOE COUNTY AND ST. LUKE'S HOSPITALS.

CASE I.—William E., thirty-one years old, white, ranchman by occupation, was admitted to St. Luke's Hospital on the evening of January 22, 1895, with supposed typhoid fever. It was impossible to obtain any facts in regard to the family history, and the patient's mind was so clouded that the personal history was very imperfect. He had led a very irregular, dissipated life, had indulged in alcohol for a number of years, and had contracted syphilis four years previously. It was learned, after his death, from a brother who had come from a distance, that several months before he had received a blow on the right side of the head which rendered him partially unconscious for some time, and that after recovering from the immediate effects of the blow he returned to work on a ranch, but frequently complained of dizziness and great weakness. It is important to remember that this information relating to the blow on the head was not given until after the patient's death, and was obtained by the brother of the patient from the friends of the sick man with whom the latter was staying at the time of the injury.

The only history that I could obtain on the patient's admission to the hospital, other than a meager account of his habits and syphilitic infection, was that he had suffered from headache for about two months. About the middle of December, 1894, his headache became intense, almost constant, and the pain was localized on the right side of the head, principally in the frontal region, but occasionally extending back to the occipital. Soon after this he was confined to his bed in an out-of-the-way place, where he could obtain no regular medical attention, and up to the time he was brought to the hospital he had remained in this condition, suffering from headache, loss of appetite, and great prostration. During this time he had emaciated rapidly and was supposed by his friends to be suffering from typhoid fever. To get him to the hospital it was necessary to bring him a distance of thirty-five miles, during intensely cold weather, in a wagon that was only partially covered. He was at first placed under the care of the general medical attendant, but, on account of the patient's severe headache and paresis of one side of the body, I was asked to see him in consultation with Dr. Sewall, the attending physician at the hospital at the time, and Dr. Munn, who was called in because it was found impossible to pass a catheter into the bladder on account of an old stricture.

An examination was undertaken at about 10 P.M., two hours after the patient was brought to the hospital. When left alone the man lay in bed, breathing quietly and apparently sleeping; on being spoken to he would rouse up for a moment and answer a question, but mental concentration was found to be impossible. His attention could only be secured for a few seconds at a time, when he would again relapse into a semi-conscious condition. The left arm and leg were much weaker than the right, with a tendency to flexor contraction of the arm at the elbow. The face did not seem affected. The right knee-jerk was increased; the left greatly exaggerated. Ankle-clonus was absent on the right, but decided and continuous on the left. The right plantar reflex was very slight, the left absent. The right cremasteric was present, the left absent. The extensor reflexes of the forearms were normal on the right; exaggerated on the left. The biceps and triceps reflexes were normal on the right; exaggerated on the left. On account of the man's mental condition it was found impossible to test the acuity of vision, but he was found completely hemianopic in the left half of each visual field. All of the external and internal ocular muscles seemed to be about normal, except that the pupils responded slowly to light. Careful test was made for Wernicke's pupillary reflex, but this was not found.

All forms of sensation seemed to be lessened or almost destroyed in the left arm and leg and throughout the left side of the trunk, but slight irritation of the left side of the face was felt; sensation was, so far as I could determine, normal on the right side. Hearing with the watch, R. = 1/2; L. = 1 4; the tuning-fork was heard better with the right than with the left ear. The man was able to smell asafetida with either nostril, but the mental condition was too much obscured to compare the acuity of smell on the two sides; neither was it possible to test satisfactorily the sense of taste. Dynamometer: R. = 112; L. = 0. On further examination the left arm was found firmly adducted to the chest by contractures of the pectoral muscles, and this continued during sleep. Both optic nerves showed slight swelling, with considerable atrophy, narrowing of the arteries, slight tortuosity of the veins, and almost complete obliteration of the normal line of demarcation between the nerve and the retina. The swelling of the optic disc amounted to one diopter in each eye. The temperature was 97.4°; the pulse 40; the respirations 16.

There was a very tight stricture of the urethra, and, on account of the difficulty of inserting a catheter, Dr. Munn fastened one in the bladder. The urine contained pus, albumin, and renal casts.

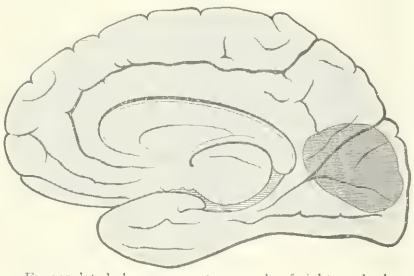
The man was placed upon inunctions of blue ointment and rapidly increasing doses of potassium iodid, on the supposition that his brain-lesion was due to syphilis. The next morning it was found almost impossible to arouse him. The temperature was 97° in the right axilla and 98° in the left; the pulse 52; the respirations 12. By noon unconsciousness was complete and beginning Cheyne-Stokes respiration was apparent. At 1 P.M. the temperature in the right axilla was 97°, in the left 98°; the pulse 46; the respirations 16. The left arm and leg had become rigid, and the man soon passed into a state of deep coma, and gradually sank, and died on the morning of the 28th, about five days after I first saw him.

During the first three days of the patient's stay in the hospital his temperature was subnormal by 1° or 1.5° on the unaffected side, and about 0.5° on the paretic side, whose muscles were contractured and rigid. Pulse and respiration were slow, the latter at times being only ten per minute. During the first three days the pulse was never found above 50, the average frequency being about 44, although occasionally it was as low as 40. At no time was there complete paralysis of the arm or leg,

but both were in a paretic condition, and the muscles rigid and contractured, and this condition increased up to a day or two before dissolution. On the fourth day the temperature reached normal, the pulse 64, the respirations 20. On the fifth day the temperature was 100.4°, the pulse 136, the respirations 48. On the morning of death the temperature was 104.6°, the pulse uncountable, and the respirations 56.

An autopsy was held six hours after death by Drs. Axtell and Freeman. The dura was normal in appearance and in attachment to the bones, and no adhesions between it and the thin membranes existed. The superior longitudinal sinus contained a soft white clot in its anterior portion. The coagulum was an inch-and-a-half long and non-adherent. All the other sinuses were free from clots or other evidences of disease. On removing the dura the cortical veins over the left convexity were found to contain dark non-adherent clots. All the cortical veins were distended with fluid blood. No evidence of disease of the pia was apparent. The walls of the right middle cerebral artery presented several thickened areas before giving off the nutrient arteries to the great ganglia. On exposing the interior of the right cerebral hemisphere by several longitudinal incisions a large abscess, oblong in shape, about two-and-a-half inches in width, was found encapsulated in the centrum ovale of the temporal and parieto-occipital region. The purulent accumulation extended forward from the cortex of the posterior portion of the occipital lobe to a point half-an-inch or more in front of the parieto-occipital fissure. About a quarter-of-an-inch of brain-substance intervened between the abscess and the posterior horn of the lateral ventricle. Neither the ganglia nor the cortical substance of the brain was directly invaded by the abscess. The capsule was dark, almost black, quite thick and had not ruptured. The pus, thin in certain portions and rather thick in other places, especially near the walls of the capsule, was light olive-green in appearance, and of a very offensive odor. The brain-substance was softened from the posterior portion of the

FIG. 1.



Encapsulated abscess in centrum ovale of right cerebral hemisphere.

occipital lobe forward to the region of the insula. The softening included both the cortical and the white substance, and to some extent also the great ganglia. The left hemisphere, the ventricles, the cerebellum, pons, and medulla showed no evidence of pathologic change. The bones of the nose and ear, on careful examination, were found free from disease. Unfortunately the body had to be shipped a considerable distance for burial and permission could not be obtained to examine any organs besides the brain. I neglected to have culture-tests made with the pus.

The difficulties in the diagnosis of the exact nature of this case, even if aided by an accurate history, would have been very great, but in the absence of this important aid they proved insurmountable, although, on learning, after the patient's death, the history of the injury to the head, I was not surprised to find an abscess at the post-mortem examination.

The three pathologic conditions discussed in attempting to reach a diagnosis were thrombotic softening, tumor, and abscess. The history of syphilis was in favor of thrombosis, but the severe headache, extending over a period of one or two months, the rapid emaciation, and the slow pulse and respiration seemed sufficient to exclude such a lesion. Normal or subnormal temperature may be associated with slow softening following occlusion of a cerebral vessel. From a number of observations, extending over a period of several years, I have been led to conclude that a sustained temperature of from a half to one degree higher on the paralyzed side than on the unaffected side, several weeks after the paralysis has become manifest, points to an irritative lesion of the brain as the cause of the paralysis. The choking of the discs was conclusive evidence of increased cerebral pressure, and I did not hesitate to exclude a vascular lesion from this symptom alone. Gowers states that choked discs may sometimes follow embolic occlusion of an artery, but such an occurrence must be exceedingly rare, as I have not observed it, although I have for more than fifteen years carefully and repeatedly examined the fundi of the eyes of every patient coming under my observation suffering from embolism of a cerebral artery.

The history of syphilis and of severe headache was in favor of a syphilitic growth, but the swelling of the optic discs was less than is commonly found associated with tumor. The marked emaciation and the low typhoid state could not be accounted for by the presence of a cerebral growth, but such phenomena are frequent results of renal disease, and these had their origin in this case, in all probability, in the stricture of the urethra and a sequential cystitis. Low temperature is common in tumor or abscess of the brain, and I have not infrequently found the temperature higher on the paralyzed side in hemiplegia of several months' duration, caused by a growth in the brain. In the absence of any obtrusive cause of suppuration a provisional diagnosis of a syphilitic tumor of the brain was made, and the patient was treated accordingly. I have rarely found muscles that were paretic, or almost completely paralyzed, become rigid and remain so for several days from the irritation of a cerebral growth, although I have observed this condition in several cases of abscess of the brain. The rigidity of the weakened muscles was well marked in this case, and it increased in intensity until a few hours before the patient's death. After obtaining, subsequent to the patient's death, the history of a blow on the head and an account of the symptoms that followed, including mental dulness, a confused feeling, and severe pain in the head, together with dizziness and emaciation, I was not surprised at the autopsy to find an abscess instead of a tumor.

The right lateral homonymous hemianopia, hemi-

paresis, and partial hemianesthia, without the involvement of the other special senses, enabled me quite definitely to locate the lesion. Had an abscess been diagnosticated on the patient's admission to the hospital, his extreme prostration and renal and cystic complications precluded any hope for relief from evacuating the contents of the abscess.

The probable source of infection was an injury to the tissues of the scalp, although this is merely speculative in the absence of a more thorough post-mortem examination, which was not possible under the circumstances.

CASE II.—John S., seventy-five years of age, white, a widower for a number of years, born in Ireland, by occupation a laborer, of large physique, resident in Colorado since 1870, was admitted to the Arapahoe County Hospital, January 22, 1895. The family history, so far as I was able to learn, was unimportant. His health in childhood had been good, and he had had no serious illness until his seventieth year. Earlier in life he had indulged rather freely in alcohol, but only rarely during the preceding five years. He denied syphilis, but admitted an attack of gonorrhea twenty years ago. He received a bullet-wound in the left shoulder in 1861 while in the army. With the exception of the time during which he was disabled on account of the wound he said that he was never sick a day in his life, until twelve years ago, when he was kicked on the left shin. The injury was attended with great pain. Later a large ulcer developed, which nearly healed at times, but for a number of years he had had a large open sore on this leg. One month before coming to the hospital, however, the ulcer completely healed, leaving a large, dark-colored, rough cicatrix which was very tender upon pressure. For some years the man had suffered from vague rheumatoid pains in the legs, especially in the knees and ankles, and in the entire left leg he had had a feeling of numbness for about five years. This leg seemed to him awkward, but he was able to walk with the aid of a cane. For a number of months there has been partial inability to control the bladder, and frequently he would soil the bedding and his clothes, and had to evacuate the bladder several times during the night. The patient says that he was struck over the lower portion of the back and nates by a cable-car early in January of the present year. He was able to rise and walk immediately afterward, and he did not think that he had sustained much injury, although pressure over the lower portion of the back gave him considerable pain. From the time of the accident he lost all control over the bladder, and the left leg was very weak. The left arm had been noticed to be weaker than the right. The patient had been obstinately constipated for a number of months. The right pupil, which was widely dilated and immobile, had been so for a number of years in consequence of an injury to this eye received eleven years before.

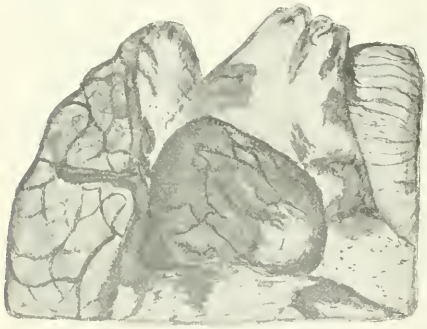
On examination, January 22, 1895, it was found that the man was unable to stand on account of the weakness of the left leg, and the examination had to be conducted while the patient was lying in bed. An old scar was observed on the anterior surface of both legs below the knees, and was evidently the result of old ulceration. The arteries of the extremities were hard and unyielding. The left leg was very weak, but could be moved at all the joints, although the power was feeble and the movements were ataxic. The muscles of the ankle of the left leg were weaker than those of the knee, and the latter weaker than those of the hip. Muscular power seemed to be fairly good in the right leg. The left arm was weaker than the right. Dynamometer: right, 100; left, 40. There was slight rigidity in the left arm, with a tendency to hold the arm close to the side of the chest and flexed at right-angles at the elbow. The mental condition seemed feeble; concentration of mind was very difficult; and it was almost impossible to keep the attention on one subject for more than a few minutes at a time. There was considerable loss of sensation throughout the left side, apparently more pronounced in the arm and leg than in the face. The knee-jerks were present, the left slightly increased, while the right was less than normal. The plantar reflexes and the tendo-Achillis reflex were present; ankle-clonus was absent. The cremasteric and the abdominal reflexes were absent. The external ocular muscles seemed to act normally. The right eye was cataractous, the pupil being widely dilated and not responding to light or in accommodation. The left pupil was very small, and did not respond to an active mydriatic, so that an examination of the fundus of either eye was not possible. There was apparent left lateral hemianopia of the left eye; the fields of the right could not be tested on account of the presence of the cataract. The mental hebetude was too great to permit of an accurate examination of the special senses.

The temperature was 98.2°; the pulse 60; the respirations 24. During the first week of the man's stay in the hospital his temperature varied from 98° to 99.2°, usually being about 98.4° in the morning, and from 98.8° to 99° in the evening; the pulse ranging from 54 to 90, only falling to 54 on one occasion, to 60 on three, and to 66 on two, the usual variation being from 72 to 88; the respiration varied less than the pulse, ranging, except on two evenings, from 18 to 20. A record of temperature, pulse, and respiration was made twice daily. During this week the man gradually failed both mentally and physically. He soon lost all continuity of thought, and his mind was a complete blank for any event of recent occurrence. He ate but little, emaciated rapidly, and passed the discharges from the bladder and the bowels into the bed. During the second week, from January 29th to February 4th, there was continued gradual failure. The temperature ranged from 98° to 99.4°; the pulse between 60 and 80; the respirations between 18 and 20. During the third week prostration increased rapidly, and the mind became a total blank. The temperature was a little lower than during the preceding week, rising above 98.4° only once, when it reached 100° one evening, but most frequently it registered 98°. The pulse varied from 70 to 96, averaging about 80, and was weak and compressible; the respiration ranged from 20 to 36. The rigidity of the left arm and of the leg-muscles became more pronounced. On February 12th the patient passed into a deep comatose condition, the muscular rigidity began to relax, and at 5 P.M. the temperature was 99°, the pulse 100, the respirations 24. The next morning at seven o'clock the temperature had reached 101.4°, the pulse 120, the respirations 40; and at 5 P.M. the temperature was 105°, the pulse 130, the respirations 36. Death took place during the night.

The post-mortem examination was made about twenty hours after death by Dr. Leonard Freeman,

pathologist to the hospital. The dead-room was cold and the body thoroughly frozen. Unfortunately, only the contents of the cranial cavity were examined. The adhesion of the dura to the bones was not abnormal. The membranes and the cortical surface of the brain, on both the convex and basilar surfaces, showed no evidence of disease. The vessels were atheromatous, but not to a pronounced degree for one seventy-five years old. On sectioning the left cerebral hemisphere no gross pathologic change was found, but in the right hemisphere an encapsulated cavity, about two inches in diameter, containing a foreign substance presenting an appearance almost identical with orange water-ice, was found in the centrum ovale of the parieto-occipital region. The greater portion of the pathologic process had taken place in the occipital lobe. The lateral ventricle had not been broken into, but only a very thin partition of brain-substance intervened between the cavity and the posterior horn of this ventricle. None of the cortical substance of the brain had been directly involved by the foreign substance, which was so situated as to exert pressure on the right internal capsule. Dr. Bane, at my request, made a drawing of the cavity, *in situ*, before its contents were allowed to thaw.

FIG. 2.



1. Abscess. 2. Posterior horn of lateral ventricle.

No evidence of gross disease was found in any other portion of the brain. In the frozen state it was impossible to determine whether the lesion was a cyst or an old abscess. The melted contents of the cavity presented the appearance of a watery straw-colored liquid, and seemed to be the product of a cyst, but the microscope showed numerous granular and broken-down pus-cells, proving the lesion to be a chronic abscess. There was no odor. After warming the brain the right hemisphere was found to be much softer than the left, but the extent of the ante-mortem softening could not be determined, as brain-substance softens so rapidly on being warmed after it has been frozen. The bones of the ears showed no evidence of disease.

Although I had had an opportunity of studying this case for a period of three weeks, the presence of an abscess of the brain had not been suspected before death, and the discovery of one at the autopsy was a great surprise to me. The age of the patient, the atheromatous condition of the radial arteries, and the comparatively sudden onset of the paretic condition with the subsequent symptoms of cerebral softening, led me to diagnosticate arterial thrombosis. The temperature was normal or nearly so, as is common to both abscess and slow necrotic softening taking place after occlusion of a cerebral artery. I regret that I did not make a careful comparison of the temperature in each axilla. It is probable that the temperature would have been found higher on the paralyzed than on the unaffected side. In hemiplegia from necrotic softening it is likely that this difference of temperature in the two axillæ does not exist to a marked degree, and when present is not persistent, except possibly when the lesion causing the softening is an irritative one, as sometimes happens in acute softening from obstruction of large vessels. The history of a fall did not militate against thrombosis, as the head did not appear to have been injured at the time, and it is not infrequent for occlusion of a cerebral artery in the aged to be preceded by increased physical exertion, which may or may not be a contributing influence in the final closure of a narrowed vessel. As it was impossible to obtain a view of the ocular fundi, the condition of the discs could not be ascertained. The absence of headache was in favor of a vascular lesion, and against abscess or tumor.

In a man seventy-five years of age, presenting a hemiplegic lesion, in the absence of a growth or the history of one in other portions of the body, the presence of tumor of the brain will not be suspected.

While no age is probably exempt from abscess of the brain, the infrequency with which it occurs in extreme old age made it improbable that I should meet with it in a man seventy-five years old. Of 223 cases of abscess of the brain, only one was found at the seventieth year or over. (Gowers.) There was no discoverable cause for cerebral suppuration. There was no discharge from the ear and no history of any. The nose seemed to be free from infective material, and no evidence of a purulent accumulation in the thoracic or abdominal cavity was detected. In reviewing the history of the case after the autopsy revealed an abscess of the brain, it has occurred to me that the large open sore on the leg might have furnished the portal of entry for the infective material with which the brain-substance became infected. The ulcer had given trouble for a period of twelve years, but it had entirely healed, the man said, a month before he came to the hospital. The appearance of the cicatrix indicated that the sore had been healed several months. It is probable that as his memory for recent events was greatly impaired on his entering the hospital, events that occurred months or years before appeared to his mind of a later date. This loss of time-sense is common in dementia, especially of the senile variety. We must remember that the left leg had appeared numb, weak, and awkward for a period of five years, and for a number of months the man had lost partial control of the bladder. The capsule of the abscess and its contents indicated that several months at least had elapsed since the cerebral suppuration had begun. What part the blow upon the lower portion of the spine had to do with causing the abscess it is impossible to say. No tenderness of this portion of the spine was detected at the time of my examination. If the blow was received only two weeks before the man entered the hospital, as he states, it is quite evident that it played no part in the causation of the cerebral suppuration, but, as

before stated, his time-sense for recent events was impaired and no reliance could be placed upon his statements relating to time, especially for things of comparatively recent date.

Had the diagnosis of cerebral abscess been made on the patient's admission into the nervous wards of the hospital, I should have urged a surgical operation, as no hope could be entertained without the evacuation of the abscess, although the extreme age and prostration of the patient would seem to have precluded almost the possibility of recovery under such unfavorable circumstances.

CASE III.—E. P., a male, thirty-seven years of age, born in Germany, a tailor by occupation, had lived in Colorado four years. The family history shows tuberculosis, renal and cardiac troubles in several members of the family. The patient's health in childhood was fairly good; he suffered from measles and scarlet fever when a child, but never had any ear-trouble. His habits have been bad; he has been a free drinker; has suffered several times from gonorrhea, and contracted a hard chancre about ten years ago. He never received a blow upon the head or a severe blow upon any portion of the body, so far as he knows. About eighteen months before I saw him he suffered from a severe "cold," and this was followed by prolonged purulent bronchial expectoration. Soon after this he began to complain of headache. His general health failed; he lost health and strength, and his mental power was weakened. He consulted a physician, who, on account of his syphilitic history and head-pains, treated him with potassium iodid for a number of months. His head-pains greatly lessened, but did not entirely subside, and he continued rather weak. His appetite was poor and vacillating, his bowels were constipated, and he was unequal to his work, both mentally and physically. He found it an effort to perform the merest routine duties of his shop, and it was distressing to him to make any mental effort. He continued in this condition for some fourteen or fifteen months, when his headache again increased, mental confusion became greater, and he felt a sense of physical prostration continually. Sleep was poor; he passed restless nights, became very much emaciated, and the headache was at times distressing. The man was again treated for syphilis of the brain, and again temporarily, but only slightly, improved in health. He became drowsy and had to discontinue his work. With the exception of taking occasional short walks, he remained in his room the most of the time for two or three days. After passing a rather restless night he arose in the morning to dress himself, but before he had completed his toilet he fell to the floor, and when found, several hours afterward, he was mentally confused and unable to rise.

I saw the man a few hours later, when he was lying quietly in bed, apparently sleeping. There was a little stertor in his respiration; his temperature was about one degree below normal in the right axilla and half a degree in the left. The pulse was 60, full and strong; and the respiration was 12 per minute. He was easily roused from his soporose condition, and seemed for a moment to appreciate what was said to him; but if left alone, he almost immediately relapsed into an unconscious state. The left arm and leg were almost completely paralyzed, the paralysis being more pronounced in the leg than in the arm, but the face did not seem to be affected, and the tongue was protruded in the median line.

It was impossible to test the general sensory phenomena, but, so far as I was able to determine, sensation was less acute on the left side than on the right. Both knee-jerks were increased, the left to a greater degree than the right. The plantar reflexes were absent. Ankle-clonus was slight on the right and well pronounced on the left. The cremasteric and abdominal reflexes were barely perceptible on the right side and absent on the left. The pupils were equal and rather widely dilated, and reacted but feebly to light. There was no paralysis or paresis of the external ocular muscles. Both optic nerves were slightly atrophied, with some swelling of the discs, greater on the right side than on the left. There was apparent left lateral homonymous hemianopia, but it was difficult to test the visual fields accurately on account of the blunted mental state of the patient. The urine was free from albumin and sugar, and no râles were detected in the lungs. Headache was not spontaneously complained of, but on rousing the man and asking him if he had any pain, he said "yes," and pointed to his head. The stupor gradually deepened into coma; the temperature continued subnormal for several hours; respiration rapidly increased; the pulse became frequent; and death took place twenty-four hours after the first manifestations of hemiplegic symptoms. The temperature before death was 103° in each axilla.

The autopsy, which was held a few hours later, revealed an encapsulated chronic abscess in the centrum ovale on the right side. The abscess was oblong in shape, about two-and-a-half inches in its long diameter by two inches in its transverse. It was surrounded by dense fibrous walls, and extended posteriorly well into the occipital lobe, and anteriorly into the centrum ovale of the tempero-sphenoidal and parietal lobes. The cortex of the brain was not directly involved, nor was the internal capsule, but a thin layer of brain-substance intervened between the lateral ventricle and the abscess. The pus was thick, greenish, and offensive. The entire right side of the brain presented an edematous appearance. No pathologic changes besides these were found in the brain. On examination of the mastoid cells and the interior of the petrous portion of the temporal bones no evidence of disease was discovered. Permission was not granted to examine any other portion of the body.

It is impossible to discuss the probabilities of arriving at a diagnosis during the time of the formation of the abscess, which possibly dated back some fifteen or eighteen months before the patient's death, or about the time of the beginning of the head-symptoms following a purulent discharge from the lungs. When I first saw the man, a few hours previous to his death, the diagnosis lay between a vascular lesion, tumor, and abscess. The eye-changes were sufficient to exclude a vascular lesion as a cause of the prolonged symptoms. The syphilitic history and the marked amelioration of the symptoms from the use of potassium iodid pointed to a tumor of a syphilitic nature, but the choked discs presented less swelling than is commonly observed in cases of progressive tumor of the brain. I have previously reported[1] a case whose history was somewhat similar to that in this case. In that patient the swelling of the

[1] THE MEDICAL NEWS, March 10, 1894.

optic disc was well marked, a tumor was diagnosticated, and the autopsy revealed the presence of a growth, connected with which was a small focus of suppuration. Nothwithstanding the strong probabilities of a syphilitic growth, the history of a purulent bronchial discharge immediately preceding the development of cerebral symptoms and the slight swelling of the optic discs determined me to venture the diagnosis of chronic abscess.

On first seeing the patient an operation was out of the question, as he was then dying from edema of the brain, which had resulted from the existence of the abscess. A post-mortem examination of the lungs would have been interesting and might have aided in determining the source of the infection, but unfortunately a thorough investigation was denied.

The three abscesses, an account of which has been given in this paper, all occurred in the right cerebral hemisphere, all occupied nearly the same position in the centrum ovale, were all attended with left lateral homonymous hemianopia, with great weakness of the left arm and leg, the loss of power being greater in the leg than in the arm, the face escaping almost entirely, and with sensory impairment on the left side. The infective material in two was probably derived from distant suppuration, and in one from an injury of the scalp, although the incomplete post-mortem examination renders this uncertain.

THE CONTINUED FEVER OF ENDOCARDITIS.[1]

By WILLIAM S. DISBROW, M.D., PH.G.,
OF NEWARK, N. J.

THE subject to which I desire to call attention presents points of interest that I consider worthy of note, on account of its rarity (judging from reported cases), the difficulties associated in its diagnosis, the length of time it involves, and the various views held by different diagnosticians of recognized reputation.

The first case of which I find record is that of Dr. Mullin, of Hamilton, Ont., quoted by Professor Osler in his report of a case under his care, and which is in many respects closely similar to the one that I desire to report.

In June, 1892, I was called to see a woman suffering from some slight pharyngeal trouble, but was unable to account for the rigors and fever with which it was associated, all out of proportion to what would be expected, even assuming the throat-condition to be other than benign in character. The patient had for three months previously been under the care of a physician of long experience and of sterling worth, who had recognized that she had valvular heart-disease, but owing to his illness and death I became the medical attendant. She had at the time of my first visit a slight pharyngo-laryngitis, which soon yielded to proper treatment; but I was surprised to find that the fever continued, together with marked debility, greater in degree than would be anticipated in such an apparently trifling illness.

On further inquiry it was learned that the woman was forty-five years old and married. Her father had died from pyemia, secondary to an accident to one of his fingers, and her mother had died at the age of fifty-six years, of pulmonary tuberculosis, secondary to pneumonia.

About twelve years previously the patient had had a severe attack of articular rheumatism, from which she suffered for several weeks; but from that time had been in fair health, with the exception of more or less pain in various joints of the body and stomach, and what had been diagnosticated as gastralgia by Dr. Janeway, of New York, whom she had consulted; he at that time recognized the valvular trouble, but considered it as the sequel of her rheumatism, and that it was not accountable for the pain from which she was then suffering.

The fever continuing—constantly for days, then intermitting—latent tuberculous trouble was suspected, and a careful physical and bacteriologic examination was made, but nothing was found to indicate this as being the cause of the fever.

Malarial toxemia was next considered, owing to the character of the fever; the chills, which had become more numerous than before, sometimes recurring daily, and at other times being of a tertian type; the temperature ranging from 102° to 102.5°, but without intermission, occasionally in the morning 102° or 103°, but during the afternoon lower. Treatment for malaria was instituted, and pushed to the utmost limit for about a week, but with no result, the fever showing no appreciable change, while the chills, though slighter in character, were not controlled.

The symptoms having thus continued for about a month without improvement, Dr. Lippman, of New York, was called in consultation, but could find no apparent cause for the condition.

Meanwhile the patient was able to be about, and had sufficient strength to walk, and even to take short rides into the country. It was thought advisable to send her out of the city, and this was done. Mt. Pocono was selected as being the most suitable place, but after staying there for about three weeks she returned, but without improvement. She then for some time resided at Lakewood and also at Asbury Park, N. J., but with no resulting improvement, except a slight gain in appetite, and an altered mental condition, which had been tried to its utmost, and discouragement was now displacing hope.

In August the woman complained of pain in the shoulder and ankle, which were slightly swollen, and soon more marked rheumatic symptoms developed, with an increased pulse and higher temperature, with occasional chills. These symptoms soon passed away, only to return again in a week or so, although at the time the treatment was of an anti-rheumatic character.

Suspecting—although nothing indicated any trouble of a surgical character—that I might have overlooked some foci of suppuration, Dr. Weir, of New York, was called in consultation, and upon careful examination found no surgical cause for the trouble, and expressed his inability from his standpoint to enlighten me, but he favored the diagnosis of malarial poisoning.

Dr. Edward J. Ill, of Newark, a gynecologist of wide experience and ability, was now called, but could find nothing in the genital organs to account for the very annoying condition with which we were confronted. Dr. Ill and myself, upon examination of the chest, thought we could detect slight dulness in the right infrascapular region, and considered that it might be due to pleuritic adhesions, if not to some more extensive infiltration of the lung-substance, and again the question arose, Was the trouble not tuberculous?

[1] Read before Practitioners' Club, March, 1895.

The valvular lesion was of course noted by all, but was not considered as bearing a causal relationship to the present illness. The fever continued without signs of abatement; at times the temperature would show some indications of remaining at the normal, but only to rise to a higher level.

In November, while in despair as to what to do, it struck me that the heart might be primarily at fault. I made a diagnosis of endocarditis, possibly ulcerative, on the ground of the well-known heart-trouble, the recurrent attacks of rheumatism, the character of the fever, and by excluding all other conditions likely to give rise to similar symptoms. Salicylates were again tried more persistently, and for the first time since June the temperature was reduced for a few days to normal, and at times below normal, but it could not be kept down, rising on an average to 99° or 100° during the day.

Being now satisfied of the correctness of my diagnosis, Dr. A. L. Loomis, of New York, was asked to see the case in consultation. Upon careful examination he found no evidence of tuberculous trouble, and, while admitting that the valves of the heart were damaged, considered that they had nothing to do with the fever, and that the case was one of auto-intoxication, due to a gouty or rheumatic condition of the patient, and recommended thorough intestinal antisepsis. All of these suggestions were carried out, but without result. The fever continued the same; the urine was normal; the nutrition was fair, although the patient was getting weaker. These conditions continuing a few weeks longer, Dr. George S. Ward saw the case in consultation and considered malarial poisoning as the possible cause.

In January, 1893, the patient began to fail rapidly. The temperature could be kept near the normal with salicylates or quinin, but the heart-sounds were rougher, and the condition was becoming alarming, the temperature at times rising to 103° or 104°, and chills recurring every day or two. Everything that could be suggested was tried, but in vain. About one week previous to death the patient had a severe chill, followed by a temperature of 104.5°; the face became slightly edematous, the ankles and legs swollen, the pulse weaker and showing signs of failing compensation; the urine scanty, albuminous, and bloody, and it was evident that the end was near. Dr. J. C. Young, of Newark, was in attendance the last few days of her life, and concurred with me in the diagnosis of endocarditis.

On February 24th the mind was cloudy; the urine became still more albuminous and bloody, the edema more pronounced, and death took place in coma on February 26, 1893.

An autopsy was held nine hours after death, with the assistance of Dr. Young. The body was fairly well nourished. The liver and spleen were enlarged and hyperemic. The spleen weighed about twenty ounces, and upon its superior border was an old infarction about the size of a silver half-dollar. Lungs, pleura, and bronchial glands were normal. The pericardium contained about four ounces of fluid and was marked with some old inflammatory scars.

The heart was hypertrophied; the mitral valves were greatly eroded and studded with large granular deposits; the chorda tendinea of the middle valve was so eroded as to be entirely severed, the free ends hanging into the cavity.

The kidneys were engorged, and were of the large white variety. The rest of the body, with the exception of the brain, which was not examined, was to all appearances normal.

With the post-mortem findings as noted, the only inference to draw is that in the presence of an old endocarditis may we not have had an acute inflammation of an ulcerative character grafted upon it, and that the case is one of those rare instances in which long periods of fever are associated with indications of heart-trouble.

Strümpell[1] states that "the recurrent form of acute endocarditis consists of an acute increase of the endocardial process, brought on by some exciting cause in an organ already suffering from endocarditis. The acute disease may show all the gradations from the mildest grade to the severest forms. The mild cases often run their course without any special symptoms. To this form we must probably often refer the increase of fever, which lasts a longer or shorter time, and which we often see in patients with chronic valvular disease of the heart. In rarer cases the recurrent endocarditis comes on quite suddenly in the form of a severe acute disease. This sometimes seems to be clinically a primary, independent disease, especially if the previous chronic heart-disease has up to that time caused no special symptoms. The patient is attacked with general malaise, headache, chills and fever. The latter may be quite high—104° (40° C.) and over—or moderate, varying between 100° and 102° (38°–39° C.), or it may be entirely absent. In many cases it is intermittent when the increase is often associated with a chill. The symptoms in the heart may be quite pronounced, but in this form, too, they may be obscure and indefinite. The course is rarely rapid, and often lasts for weeks. In the further course of the disease we meet with cutaneous hemorrhages, retinal hemorrhages, articular swellings, large renal hemorrhages, or typical hemorrhagic nephritis—in short, just the same general type of disease as in the other malignant forms of acute endocarditis."

In considering the history of these most interesting cases, we are prone to ask why they should be considered as acute; for certainly a valvular trouble lasting a year would be more appropriately classed as chronic, and on this point Osler, in commenting upon the case of Dr. Mullin, in which the fever lasted for more than a year, and in which the autopsy showed extensive vegetations upon the mitral valves, states that the term acute is scarcely applicable to them, and further remarks that cases in which patients with chronic valve-disease are attacked with marked fever, and evidence of recent endocarditis, may present symptoms of a pyemic or a typhoid character and may run a most acute course, but those lasting weeks or months assume rather a chronic character. Quoting from Loomis, Osler states that when an individual already suffering from valvular disease of the heart is attacked with acute rheumatism the liability to acute endocarditis is increased, and even when rheumatism is absent acute endocarditis is liable to occur in the presence of old valvular disease.

In reviewing the case here recorded, the temperature-range, extending over nine months to my personal knowledge, during which a careful record was kept, was the most pronounced feature, averaging from 101° to

[1] Text-book of Medicine.

101.5° throughout that time, the chills and the articular symptoms being concomitant and troublesome.

Despite the old valvular trouble, followed by acute attacks of endocarditis, the cardiac compensation would possibly have continued for a still longer time had not the rupture of the heart-muscle brought on the crisis. The lesson to be learned from this case is that we must not be satisfied to ignore old valvular lesions of the heart, but should be watchful lest they assume renewed activity.

151 ORCHARD STREET.

EXPERIMENTAL NOTE.

SOME EXPERIMENTS WITH TEA.

BY PETER McKECHNIE, M.D.,
OF TALAWAKELA, COLOMBO

THE following results may be interesting to members of the profession. They represent the outcome of an inquiry into the action of tea on the digestive organs.

The trial-experiments were carried on with test-tubes, a digestive fluid being prepared by making a glycerol extract of pepsin. The aliment used consisted of beef-fiber and egg-albumin. Measured quantities of each were used, and to six test-tubes containing the meat-fiber were added the glycerol extract and hydrochloric acid, also a measured quantity of tea, different lengths of time being given to each infusion, varying from five to twenty minutes, so that the different test-tubes each had a different degree of strength of tea. A seventh tube was used to fix the time required for the digestion of the meat-fiber alone, which proved to be about 110 minutes. With the tea added to the other test-tubes the time required for the digestion of an infusion of twenty minutes was the same as with one of five minutes, namely, 118.5 minutes. Another experiment was made on the same basis, but with the tannic acid precipitated by means of a gelatin solution. The result of this showed no appreciable difference in the time taken to digest that with tannic acid and that without tannic acid.

The experiments were carried still further by means of a gastric fistula formed in a monkey's stomach. It was found on introducing the ingesta by the mouth that digestion was retarded about five minutes longer than when the ingesta and the tea were introduced through the mouth and the fistula respectively, thus showing that the tea exerts an inhibitory influence upon the salivary glands. When the tannic acid was precipitated and introduced in the same manner there was no difference in the time occupied in the digestion of the tea without tannic acid by the mouth as compared with that by the fistula, but there was an appreciable difference on the introduction of an infusion of twenty minutes without tannic acid as compared with an infusion of five minutes with the tannic acid removed. The peristaltic action was retarded and the secretion of gastric juice diminished. I am of opinion that the tannic acid in the tea is not the injurious agent, but some of the less soluble extractive matters.

With a view of ascertaining the value of the teas of different countries as dietetic agents I procured samples of Chinese, Ceylon, and Indian teas, and carried on experiments with them, an infusion of equal quantities of each kind being used. The Indian and Ceylon teas gave a much stronger infusion in five minutes than the Chinese teas; I found that digestion took place more quickly with the stronger infusions than with the weak. The secretion of gastric juice was increased considerably with the Indian and Ceylon teas.

The reason I attribute for this is that Indian and Ceylon teas contain a much higher percentage of caffein than Chinese teas, thus acting as a stimulant to the motor nerves and increasing the peristaltic action and flow of gastric juice.

From the results of my observations I am inclined to think that the action of tea is not so injurious as some would like to make it out. It is greatly dependent on the method of infusing, whether its action is injurious or beneficial. Long-infused teas seem to extract some substance, possibly an alkaloid, that has an inhibitory action on the nerves of the stomach. I may here state that an infusion of tea of twenty minutes with the tannic acid precipitated has the same bitter taste as the same tea with the tannic acid present, so that the bitterness in long-infused tea is not due to the tannic acid, but to some other ingredient.

The method of preparation of the tea-leaf is another point that requires attention. Indian and Ceylon teas are prepared on a more highly scientific basis than those of Japan and China. The curling of the leaf is done in the first-mentioned countries by means of machinery, by which means the cell-walls are entirely broken up; while in China and Japan the rolling is done by hand, which is a most imperfect method from an economic point of view, owing to the greater surface exposed. Through the entire breaking up of the cells in Indian and Ceylon teas, less tea requires to be used in order to get the same result as in Chinese tea; thus with three pounds of either Indian or Ceylon tea the same amount of work can be done as with five pounds of China. In my experiments I found that an infusion of Indian and Ceylon teas in the proportion of forty-five grains to ten ounces of water gave a solution of the same specific gravity as an infusion of Chinese tea consisting of sixty grains to ten ounces. The experiments carried out with these infusions showed a marked superiority of the Indian and Ceylon teas in assisting digestion. On making a microscopic examination of the leaves after drying them, I found that in the case of the Ceylon and Indian leaf the water had extracted the free tannic acid, while in the Chinese teas there could be observed needle-shaped bundles within the interstices of the cells.

I think that it would be advisable for medical men in studying the dietary of their patients to caution them against the use of long-infused teas. If a patient has tea which requires long infusion, there is something wrong, as the active principles can be extracted in five minutes from really good teas. Longer infusion is most injurious; in fact, with Indian and Ceylon teas three minutes are quite sufficient. I shall continue my researches, and intend to study more of the chemistry of tea and its physiologic action on the nerve-centers.

Eye, Ear, Nose, and Throat Clinic is the title of a new quarterly publication emanating from Kansas City, Mo., and edited by Drs. Flavel B. Tiffany and James E. Logan, and containing a department of neurology under the charge of Dr. John Punton.

NEW DEVICE.

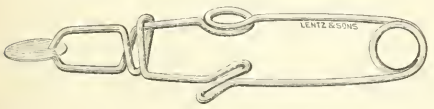
A NEW COVER-SLIP FORCEPS.

BY A. H. STEWART, M.D.,
OF PHILADELPHIA;
INSTRUCTOR IN CLINICAL MICROSCOPY, JEFFERSON MEDICAL COLLEGE.

As the microscope comes into more general use by the physician, and as the study of bacteriology has become so necessary, new devices are constantly being brought forth to aid in research. Many new instruments are needed; many old ones have become useless.

There is no one instrument that is used by bacteriologists so frequently as cover-slip forceps; but every microscopist knows how inefficient are the cheap varieties and how comparatively expensive are the good ones, and none is entirely satisfactory.

The forceps here illustrated has proved in my work more generally satisfactory than any other yet seen. It is made of coppered steel wire or German silver wire, and can be manufactured for about one-fifth the cost of the orignal Lindslay or the Cornet nickel-plated steel forceps, and is just as steady and durable. The spring is sufficiently strong to hold firmly a slide or cover-glass without allowing it to move from side to side and yet



not powerful enough to break the glass. The blades of the forceps are locked, thus giving a perfectly steady movement and constant apposition when not in use. The extremities of the blades are small and circular and are made in such a way that the cover-slip held in position has a slight inclination downward away from the instrument, so that the stain when placed upon the cover-glass does not run down on the lower blade of the forceps, even when the blades are moist.

When placed upon the table there is no tendency for the instrument to upset, the base being more than an inch wide, and when placed upon the side the cover-glass escapes injury, not striking the table because that end of the forceps is overbalanced by the other.

The comparative cheapness and durability of this forceps will recommend it as a most valuable instrument, not alone for ordinary private work, but in large laboratories where many men are at work, and large numbers of such instruments are required.

It is manufactured by Bausch & Lomb, of Rochester, N. Y., and can be procured from dealers in microscopic supplies in Philadelphia.

250 NORTH TWELFTH ST.

MEDICAL PROGRESS.

In the Treatment of Fracture of the Patella FOWLER (*Annals of Surgery*, vol. xxi, No. 6, p. 627) recommends exposure of the fragments after the immediate effects of the injury have subsided, and before the occurrence of ligamentous union, for the purpose of clearing their surface of intervening soft parts, and the application of fixation-hooks somewhat resembling Malgaigne's, except that a single instead of a double pair is applied. The parts are kept at rest for from fourteen to twenty-one days, or sufficiently long to permit of the subsidence of the effects of traumatism upon the surrounding structures, as well as the closure of a possible rupture of the upper recess of the capsule of the joint. During this period of waiting the time is advantageously occupied by daily cleansing of the parts with soap and water, and the application of gauze compresses wet with boro-salicylic solution, secured in position with a figure-of-eight bandage.

The operation-wound, by which access is gained to the fracture, is placed either transversely or vertically; if transverse, it commences at the inner edge of the patella slightly above its middle, curves sufficiently downward to include beneath the flap the line of fracture, crosses the front of the lower fragment just above the attachment of the ligamentum patellæ, and ascends to terminate at a point opposite the place of commencement. The half-moon-shaped flap thus marked out is dissected back just far enough to expose the line of fracture and no further. Careful and systematic removal from between the fragments of the intervening mass, consisting of stretched and torn shreds of fibrous tissue and partially organized blood-clot, is now practised. This is greatly facilitated by first incising along the free margin of each fractured surface and loosening the mass at these points first. The blade is now slipped between the mass and the fractured surfaces, and the former freed from the latter without difficulty, and removed as one piece. Care is taken during this portion of the operation not to tilt or otherwise disturb the fragments, and to expose the joint-surfaces as little as possible. No irritating fluid should be employed; whatever portions of the *débris*, blood-clots, etc., which may chance to fall into the gap between the fragments, and cannot be picked out by the dressing-forceps, may be removed with bits of sterilized gauze grasped between the blades of hemostatic forceps.

The fragments are now made to approximate each other as much as possible. One of the fixation-hooks is thrust into the bone at the site of the attachment of the ligamentum patellæ to the lower fragment. The other is pushed through the skin and into the bone at the site of the attachment of the rectus femoris to its upper border. With the fractured surfaces in perfect coaptation, as seen with the flap still turned back, the shanks of the fixation-hooks are drawn together and secured, and the fragments held in a most secure manner. Two or three very fine silk sutures may be employed to secure the edges of the soft parts along the line of fracture. The flap is now replaced and sutured with a continuous subcuticular silk suture. Sterile gauze-dressings and non-absorbent cotton, secured in position by rollers, are applied; and a plaster-of-Paris splint insures immobilization. If the curve of the transverse incision is properly managed, the lower hook will be so placed as to secure the bone directly in the line of the incision, thus avoiding the passage of the former through a wound of its own in the skin. If the vertical incision is employed, both upper and lower hooks can be secured in the bone in the line of the incision. The transverse incision (U-shaped) gives better access to the parts if well curved.

The fixation-hooks are permitted to remain for about

three weeks. Should it become necessary for any reason to remove them earlier, this can be done by opening the splint at the anterior knee-portion. The patient may recline, or sit, or go about in a wheel-chair during the convalescence.

Colectomy.—PAUL (*British Medical Journal*, 1895, No. 1795, p. 1136) details eight cases of colectomy for various conditions, and summarizes his views as to those which are most suitable for operation and as to the best methods of accomplishing this. He believes that young subjects with a comparatively short history, who are passing mucus and blood in the stools, and in whom the tumor is large enough to be felt, are the cases in which the growth is most malignant. Unless very large, the affected part can be safely removed, but recurrence must be expected. Older people, upward of forty-five years, with generally a longer history of gradually increasing constipation, frequently culminating in absolute and sudden obstruction, often have a ring-stricture, which is much less malignant, and when satisfactorily removed may undoubtedly be followed by permanent cure. Expression is given to a personal willingness to remove the growth in almost all cases in which there are no secondary deposits, but those who wish to select carefully should be content with colotomy in the former class, and restrict colectomy to the latter. Attention is directed to the frequency with which the abdominal pain (colic) and vomiting of the earlier stages of chronic obstruction are mistaken and treated for dyspepsia. The sooner the disease is recognized the better is the surgeon's chance of success.

The operation may be accomplished in two very different ways, one by immediate and one by delayed approximation, each being suitable for a certain class of cases. When the patient is in good condition, the abdomen not distended, the tumor small, and the proximal end of the bowel not greatly hypertrophied, immediate approximation by Murphy's button-method is advised. When, however, the opposite of this condition prevails, it is strongly urged that the ends of the bowel should be brought out. The important steps of the operation are as follows: 1. Exploration first in the middle line unless the stricture has been located; 2, a sufficiently free incision over the site of the tumor; 3, after adhesions have been cleared away, ligation of the mesentery with the help of an aneurism-needle and sufficient division to free the bowel well beyond the growth on each side; 4, hanging the loop of bowel containing the growth or stricture out of the abdomen and sewing together the mesentery and the adjacent sides of the two ends. The stumps of the mesentery should lie beneath the bowel, where, if deemed advisable, it can be drained by packing gauze down to it; 5, tight ligature of a glass intestinal drainage-tube into the bowel above and below the tumor and then cutting away the affected part; 6, closure of the ends of the wound with a few silkworm-gut sutures, passing through all the layers of the abdominal wall. The second stage of the operation, that of breaking down the spur with an enterotome, should generally be undertaken about three weeks later. As soon as this has been satisfactorily accomplished, the artificial anus is closed by separating the roset of mucous membrane from the skin, turning it in, and bringing the freshened edges of the latter together over it.

Absence of the Thyroid Gland in a Case of Cretinism Successfully Treated with Thyroid Extract and Fatal from Broncho-pneumonia.—BURCKHARDT (*Revue Médicale de la Suisse Romande*, June 28, 1895, p. 341) has reported the case of a child, three years old, presenting a well-pronounced clinical picture of cretinism, in which marked improvement in the symptoms and physical characteristics followed the therapeutic employment of thyroid extract. The treatment had thus been continued for three months, when death ensued in the course of an attack of broncho-pneumonia. Upon post-mortem examination most careful search failed to detect the presence of thyroid tissue, the gland being replaced by adipose tissue.

To Preserve Specimens of Urine, LEFFMANN (*Philadelphia Polyclinic*, vol. iv, No. 26, p. 271) has found chloroform to answer most satisfactorily, from six to eight drops being added to each ounce. It yields with Fehling's solution a reaction similar to sugar, but it does not react with the bismuth or the phenylhydrazin test nor prevent either of these when sugar is present.

THERAPEUTIC NOTES.

Forced Dilatation for the Relief of Diphtheric or Croupous Obstruction of the Larynx.—BORS (*New York Medical Journal*, June 29, 1895, p. 822) has treated a series of cases of laryngeal obstruction arising in the course of diphtheria and croupous laryngitis by means of forced dilatation. For this purpose he uses an instrument consisting of a three-bladed, jointed dilating-canula, attached to a bent shaft contained in an introducing-handle. After the canula has been introduced into the larynx the blades are separated by means of a screw situated under the handle. The application occupies but a few moments, and in the majority of cases a single dilatation is sufficient. Should the growth of false membrane constantly recur, the manipulation should be undertaken every two or three hours for two or three days. The same procedure may be adopted in cases of laryngeal stenosis due to syphilitic and other cicatrices. The instrument is made in three sizes, of 2½, 4, and 5 mm. in diameter.

A Simple Means of Preventing Nocturnal Enuresis.—STUMPF (*Münchener medicinische Wochenschrift*, 1895, No. 24, p. 560), from physiologic and dynamic considerations, proposes to treat nocturnal enuresis by depressing the head and elevating the hips of the sleeping child, and has employed the method in some twelve cases in individuals of various ages and of both sexes with the best results.

In the Treatment of Aneurism COHEN (*Philadelphia Polyclinic*, vol. iv, No. 27, p. 282) employs hydrated calcium chlorid in doses of about a dram a day, in conjunction with rest and other suitable adjuvant measures.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM, IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 27, 1895.

THE COMPARATIVE STANDING OF THE AMERICAN MEDICAL PROFESSION.

WE Americans have never been accused of being a too modest people. We have a due respect for our own achievements, and seldom hesitate to express it with vigor. But we are discriminating in our self-appreciation. We are just as keenly conscious of our defects as of our virtues, and as frank in bewailing them.

That is the real difference between us and the Scotchman or the German, for instance. These seldom brag, but that is merely because they are so calmly confident of their overwhelming superiority. No word from them is needed. They and theirs speak for themselves, and simply overawe with conviction any intelligent foreign mind. If you are not convinced, it's because you are not intelligent, and argument would be wasted on you. And they seldom or never invite the attention of the public to their defects, even when they see them, which isn't often.

One of the things over which we are particularly fond of indulging in jeremiads is the "low standing and standard of the profession in America." We bewail (and justly) the shortness of our college-courses, the lowness of our examination-requirements, the abundance, shamelessness, and prosperousness of our charlatans, both in the profession and out of it, and the scandalous popularity of the patent medicine. All this is perfectly true, and its recognition is good Christian discipline for us. But, not content with this, we plunge further and declare that such a disgraceful state of affairs was never known in civilized country. As usual, "they order this matter better in France," say we, and proceed to declare that in England and on the Continent all medical men are highly educated gentlemen, that self-advertising and violations of the Code are unheard of, and the patent-medicine nuisance almost abolished. And here is where we mistake. There is really no such tremendous difference as we imagine between the beam in our own eye and the mote in our European brother's. Each profession has simply the defects of its surroundings.

For instance, it is customary to declare that the quality of our profession must be poor because its numbers are so disproportionately large. We have actually one physician to every 500 inhabitants, four times as many as England (1:2000), six times as many as France, nearly eight times as many as Germany, and fourteen times as many as Russia or Spain (1:7000). Our low standards and the cheapness of our diplomas, we cry, have flooded us with a swarm of incompetent, half-educated men, whose numbers are the root of two-thirds of our troubles. If scientific Germany and decorous England are satisfied with one-fourth or one-sixth of our number, we must have a ruinous excess.

But there are other factors to be taken into consideration, and legitimate ones, too. The law of supply and demand, for instance, and the density of population for another. One competent physician is probably capable of properly performing the medical services required by 1500 or 2000 people, *providing* they are situated within a radius of three miles from his office, and for an even larger number within a mile; but what about the district where he would have to drive forty miles to reach 500 people? A physician is just as absolute a necessity to a "cow-town" or mining-camp of 300 people, and no medical aid within fifty miles, as to a factory-village of 5000. Indeed, many a "superfluous," poorly educated, uncouth country doctor, out on the frontier, with his tiny *clientèle* scattered over two counties, who loves his patients and his profession, commands as much of our admiration and respect, deserves as well of his country, and is as "necessary" in every

sense of the term as the most scholarly and polished consultant of a European center. If we were to divide this country and England each up into geographic settled districts, each requiring the residence of a physician, nearly two-thirds of our "excess of doctors" would disappear at once.

A word in this connection in regard to our low standard of professional education. This, we must also recognize, has an economic basis which, in the past, has raised it to the dignity of a practical necessity. It is not merely due to our "natural slipshod tendency." Exactly the same state of affairs prevails among our merchants, our tradesmen, our artisans—and for the same reason. In Europe a special education or years of apprenticeship are considered necessary to fit a man for any occupation or trade, even for a farmer. Here the farmer turns merchant, the mechanic, lawyer, the ploughboy, preacher, at a few months' or even days' notice—and successfully, too, as our extraordinary material prosperity indicates. It is merely a question of supply and demand. With literally scores of new, independent, and widely separated communities springing up every month, each one demanding a complete outfit of both brain-workers and muscle-workers, from judge to blacksmith, from bench to bellows, a rapid rate of production of "specialists" is absolutely necessary. The country simply couldn't have been settled *and kept civilized* without it. The wonder is that, considering the tremendous pressure under which the transformation took place, the results have been so good. On hunting-trips through the West ten or fifteen years ago it was a common experience for a doctor to be simply begged to stay in half the settlements he passed through; office-rooms, building-lots, houses even, would be offered, and when declined the urgent request would be made for a member of the next graduating-class, an office-student even, "anyone who knows how to deliver a woman and set a broken leg, for there's no doctor short of the fort, sixty miles away." Our "rapid-process" doctors have really been filling a genuine civic need of great importance. The greater part of our territory has now been supplied with its "geographically necessary" medical staff, and behold the result! A rapid elevation of the standard of education and a unanimous lengthening, nearly doubling of the course by almost every reputable medical school in the country.

The motive which led to this elevation had, of course, no connection with the economic influences, but these latter rendered the triumph of the better element possible. Just as long as a "six-weeks doctor" can go West and pick up a living practice at once so long a certain class of schools will turn out that kind and no other.

There is also another consideration in regard to our "oversupply" of physicians, which may seem at first sight fanciful, but which it seems to us has real weight. And that is, that the more highly civilized and the more intelligent a people the larger proportion of physicians will be needed. Not because disease becomes more common, but because a higher standard of health, comfort, and efficiency is demanded. There is little need for oculists, for instance, in an illiterate community, and the Cossack of the Don has little use for sanitarians or health-officers. More than this, the sensitiveness of the organism counts for much; the peasant, artisan, and even middle classes of Europe will suffer ten times as much in the way of pain, disfigurement, or disability, as our native Americans before they will consult a doctor. We seldom see "typical cases" of certain diseases described by our German and Austrian *confrères*, simply because they are not permitted to develop so long without interference from either medicine or soap. As an illustration of our meaning, it is a matter of common observation by Americans abroad that even well-educated and well-to-do Europeans will tolerate for years a condition of their teeth and gums which would be considered simply unendurable, if not actually disgraceful, here.

In short, the number of physicians is a good index of the intelligence of a race. And as civilization becomes more complex, and the whole field of preventive medicine, scarcely surveyed as yet, is added to our domain, a still higher proportion of skilled, intelligent advisers will be demanded by the community.

But, says someone, are we developing many such men or encouraging their development, or will not the mass of half-fledged living-makers overwhelm the small minority of scholars and maintain a low professional tone and standard in spite of everything? By no manner of means. The question is somewhat on the order of Carlyle's celebrated conundrum, "How can the united sagacity of fools constitute wisdom?" It is the best, the broadest, the most devoted men, from hamlet to metropolis, who sound the key-note and who set

the pace. Partly because cream always rises to the top, but, in still larger degree, because the great mass of imperfectly prepared physicians are keenly conscious of their defects and anxious to remedy them. Some, of course, fossilize into the pompous walking-dictionary of their parish, the self-satisfied oracle of admiring grandmothers, with "sure cures" for everything; but they are few and absolutely without influence on the mass. A half-educated man, who knows himself to be so, is often a much more desirable member of the profession than a well-educated man who is thoroughly aware of the fact. The former has unconsciously attained the Socratic attitude, "I know nothing, except that I know nothing; others do not know even this." There is a striking difference between the European profession and our own in this respect. The average British practitioner, college-bred and hospital-trained for five long years, with a couple of terms as interne added, usually buys himself a practice or a partnership and settles down for life. He reads his single medical journal, of course, attends his county society, goes to the British Medical Association when it comes within fifty miles of him, and occasionally revisits his old hospital, or attends a few clinics when in London with a patient. But as for post-graduate courses, even in London or Edinburgh, to say nothing of Paris or Vienna, he never thinks of such a thing. He has much to learn yet, of course, but his *education* is practically complete; experience is all he needs. There is but one post-graduate course in all London, and that was gotten up for the benefit of Americans. There are many honorable exceptions, of course (the F.R.C.S. and M.R.C.P. men, for instance); but the English practising physician who has studied abroad or taken up systematic work of any sort since his graduation is rare. Much the same state of affairs prevails in France, Germany, and Austria. Visit any great medical center and one will see ten American students to one of any other foreign nationality. The true *Deutscher* indeed would scorn to study outside of the *Vaterland*, and even consultants and teachers in Germany too often know little of and care less for the work which is being done in their own field elsewhere.

With all its faults and pretentiousness our post-graduate course is one of our most useful institutions, and the resolute determination and enterprise with which the majority of our "two-year" men avail themselves of its privileges compel our respect and admiration. No sooner is the horse and buggy earned, and the first payments made on house and lot, than our country doctor begins to lay by money to take a winter course, or even an additional year in New York or Chicago. A few years later he goes abroad, and this habit is kept up more or less through the whole of his professional life. We can scarcely go into any middle or western town of 2000 people, or even rural district of the same population, without finding some doctor who has spent one or more winters or springs in Philadelphia or New York, and not infrequently in Vienna or Paris. It is true the majority of us are imperfectly educated, but we are not ashamed to admit it, and we are doing our best to remedy the defect.

We are also accustomed to assume in the depths of our self-depreciation that our general ethical tone as a profession is far below the European one. Nothing could be further from the truth. From personal experience we do not hesitate to say that the tone of our profession as to courtesy, modesty, and ethical qualities generally is but little below that of England, and *far above* that of either Germany or Austria. The disgraceful promptness and certainty with which all new remedies and appliances get themselves patented in Germany is a case in point, as is also the attempt to cover Behring's antitoxin in the same manner. The German or Austrian is permitted to trumpet his own praises abroad, or denounce and belittle his rival brother in a way that would scandalize even the Bunkum County Medical Society. His titles and official rank are spread before the public at full length on every possible occasion, and woe betide the unlucky wight who omits the least of them in addressing him. The shower of abuse and vilification poured upon Sir Morrell Mackenzie by the court-physicians, in the case of the Emperor Frederick, even granting every possible provocation on his part, was a disgrace to the entire German profession. Fancy Agnew and Hamilton abusing Bliss after that fashion in the Garfield case, no matter what he did!

As to personal courtesies, it is no unusual thing for Austrian consultants to charge fees, and heavy ones, too, for services or even advice to visiting English and American physicians. When it comes to that truest test of a man's real breeding, his manner and behavior toward his hospital-patients, there is simply no comparison to be made between

the Continental and Anglo-American attitudes. It might be roughly summed up in one sentence: in America or England the chief object of interest and care is the patient, in Germany the disease.

Last of all, we are apt to assume that quackery is a malady almost peculiar to our own soil, and that the official lists abroad represent all the healers of disease in their respective countries. It is true the fame of the American quack is world-wide, and his luster is unrivalled anywhere in Europe; but, nevertheless, the fact remains that even the best-regulated countries in the world abound in "irregulars" of every sort and description. First of all come the apothecaries, who in many parts of England, for instance, are more numerous than the physicians, and prescribe over their counters fully one-half of the medicine consumed in the country. The "pothecary" is the first resort of the vast mass of the laboring-classes, the doctor being far too expensive to be called, except as a last and direst necessity. Then come a horde of midwives, "bone-setters," "wise women," and so forth, down to the "seventh son of a seventh son," and the man who has bought or inherited a secret formula of magic value.

As to patent medicines, although the term is one of our own coining, the goods it is applied to are cosmopolitan in their range. Though we use far more of them per capita here (as we do of all other luxuries), especially in prohibition communities, yet the sale of them in England, France, and Germany is simply enormous. Their advertisements swarm in every paper, appear upon every bill-board, street-car, and dodger, and would disfigure the landscape almost as horribly as they do on this side the Atlantic was not such defacement strictly forbidden by law. Indeed, in effrontery and in diabolical ingenuity of methods of thrusting their wares upon your notice, the French and English manufacturers are rapidly going ahead of our own. The columns of foreign papers and journals are coming to be even more heavily loaded with "ads" of this, and, indeed, of all descriptions, than our home-ones. And this latter tendency is noticeable in even the medical journals. Even some models of British journalistic propriety carry heavier ballasts of legitimate advertisements in proportion to their canvas of reading-matter than would be considered entirely *comme il faut* by one of our first-class journals.

In short, all professions, as all nations, have their shortcomings, and while we have many things to be heartily ashamed of, both as individuals and as a class, and should slacken our struggle for self-improvement not a whit, yet we think it only fair at times to take stock of our virtues as well as our vices, and to cheer ourselves with the thought that with all our shortcomings our intentions are good, our hearts in the right place, and our rate of progress distinctly appreciable.

EDITORIAL COMMENTS.

Hippophagy.—It is an ill wind that blows nobody good, and the late appalling fall in the price of horses, due to the introduction of the electric trolley and the bicycle, has turned the attention of our thrifty farmers to the question of the utilization of horse-flesh as an article of diet. None of them seems at all desirous to make the experiment himself, but they fail to see why it should not form an excellent and healthful food for somebody else. In fact, the project has been seriously considered just lately of shipping horses on the hoof to Germany, where they are sufficiently enlightened to have no prejudice against this luxury. According to Secretary Morton, nearly 10,000 horses are slaughtered every year in Germany alone for food purposes, a large proportion being used in the production of their favorite "horse-sausage." The average price paid by the butchers is about $35 a head, which would yield quite a good profit to the shippers.

Now why should we not do likewise and save the poor ponies all the horrors of sea-sickness and transportation. We copy Germany as nearly as we can in pathologic matters already. Why not also in dietetic customs? The only obstacle is mere popular prejudice against eating horse-meat. We might succeed in introducing a little of the sausage, because we are already accustomed to the use of man's next nearest four-footed companion, the dog, in that form, but as to colt-steaks and mare-cutlets there would be difficulty.

Seriously, however, why should we not add horse-flesh to our bill-of-fare? There is absolutely no physiologic or hygienic reason why it should not be as nutritious, healthful, and palatable a food as the flesh of the ox or the sheep. Indeed, there is abundance of evidence from all climes that it is the equal of beef and mutton in all three of these respects. The Tartar hordes of the Siberian steppes depend on their horses almost entirely for meat as well as milk and clothing; as also did the Scythians of antiquity. In war and in times of scarcity horse-flesh has been used hundreds of times and with most satisfactory results. During the last siege of Paris, for instance, thousands of horses were consumed, and the meat was found so palatable that dozens of butcher-shops still do a large trade in it—a trade that is steadily increasing, especially among the laboring-classes. The meat is said to be almost indistinguishable from beef, though of finer grain and more marked flavor. This is extremely favorable when we remember that most of the animals killed have been such as through age or injury were incapacited for hard work. Curiously enough, mule-beef is said to be still juicier and better flavored.

In fact, the only objection that can be raised is on the score of expense, and that has now been completely removed, as many horse-raisers would be glad to get good "beef-prices" for all but their choicer stock.

Besides being a valuable addition to the variety of our flesh-foods, in the light of recent bacteriologic developments there would be another advantage that might make the use of horse-meat of great importance to the community. This is the almost complete immunity of the horse to tuberculosis. If, in addition, a breed of horses could be developed with special reference to their milking-powers—equine Jerseys, as it were—and their milk substituted for that pernicious extract of tuberculous bovines that at present fills our nursing-bottles and milk-pitchers, what a threatening shadow would be lifted from our national future! By all means let us urge horse-flesh and mare's milk upon our patients if only to relieve the anxiety of our bacteriologic friends and save the babies from sterilized milk. Of course, from a purely scientific point of view they had better starve on that than grow fat on tuberculous lacteal fluid, but mothers and even doctors cannot see it so. Indeed, mare's milk should be a sure prophylactic against "mare's nests" of all kinds.

—

Typhoid Fever and the Brand Method.—In the report of the German Hospital of Philadelphia, recently issued, we find the percentage of deaths from typhoid fever treated in that institution during the year to be 16⅔ per cent.—78 cases with 13 deaths. The German Hospital has been the home of the so-called cold-water treatment in this country, and the beneficial results of the treatment in this institution in previous years have been largely quoted. The following table shows the number of cases of typhoid fever treated and the mortality from the year 1890, when the Brand method was introduced:

	No. of cases treated.	Deaths.	Per cent.
1890	106	5	4.7
1891	116	8	6.9
1892	71	3	4.2
1893	74	11	14.8
1894	78	13	16.6

In THE MEDICAL NEWS of November 26, 1892, Dr. J. C. Wilson reported one series of 160 cases, treated according to the method of Brand, with 8 deaths, or 5 per cent.; and another series of 66 cases, with 4 deaths, or 6 per cent. (These cases are included in the figures already given, though differently arranged.) It would be interesting to determine what has caused this unfavorable increase in the mortality-rate under the cold-water treatment. As far as we can learn, the methods have not been changed, and the disease in Philadelphia has not been especially virulent. The death-rate varies in different years. In the same hospital, previous to 1890, the mortality varied from 11 per cent. to 20 per cent.

The Pennsylvania Hospital typhoid-fever statistics are as follows:

	No. of cases treated	Deaths.	Per cent.
1890	126	22	17.4
1891	144	23	16 0
1892	104	10	9.6
1893	94	4	4.2
1894	105	14	13.3

The Presbyterian Hospital reports show the following:

	No. of cases treated.	Deaths.	Per cent.
1890	17	5	28.8
1891	39	5	12.8
1892	83	6	7.0
1893	69	12	17.0
1894	80	3	3.7

In the Pennsylvania and the Presbyterian hospitals the Brand method has been used in the majority of cases during the last two years.

There is some danger of such a method of treatment becoming routine, to the exclusion of all other treatment, and this is always to be guarded against. The cold bath has decided advantages, and when carefully given and controlled, and each case judged by itself, it is a therapeutic agency of great worth; but if it is considered in the light of a specific agency, and each patient is subjected to it, the bulk of the work being left in the hands of the nurses, there is some liability to suffer from an increase in the mortality-rate. One of the good effects of the Brand treatment is the constant watching that is required, the frequent noting of the temperature, etc.

Sixteen-and-two-thirds per cent. mortality is not a very favorable showing for the cold-water treatment, although the managers of the German Hospital in their report still seem to regard the results as most encouraging, and give large praise to the treatment. It would be interesting to conduct a series of experiments in the same hospital, at the same time, with a sufficient number of cases and extending over a considerable period of time, one group of cases to receive the Brand treatment only, another group to be treated with intestinal antiseptics, and a third group to receive the two combined; the bath for its antipyretic effect, the antiseptics for their local action.

—

Opium as a Food.—Facts are sometimes against the professional reformers. Alcohol, in spite of the evil it does, has certain uses, and is steadily winning its way back to the tables of our educated classes. Tobacco has been authoritatively declared to be a necessity of city life, and one of the great buffers of the shocks of the rush of the nineteenth century. And now even a royal commission in an elaborate report has asserted that the use of opium by the inhabitants of India has a rational hygienic basis, and is not merely one of the "horrors of heathenism." In the first place, it is, we are assured, a valuable household remedy for the intestinal diseases that swarm in that climate, as paregoric and blackberry brandy are used by our country-folk. It is also regarded by the natives as a most reliable preventive of malarial diseases, and though not so recognized by the profession it has been highly esteemed for this purpose by many explorers. The commission does not say anything about snake-bites, which proves that they are not merely engaged in furnishing excuses for the appetite of the gentle Hindoo. Further than all this the report declares that the regular consumption of opium in moderate doses fills a place in the dietary similar to that occupied with us by tea and coffee. In other words, opium is a genuine food of the "force-regulator" class (Prout), and of value especially in connection with a coarse and restricted diet and a life of hardship. Its value was proved after the grimmest fashion during the

building of the railway across Panama. One of the contractors came to the conclusion, whether upon economic or philanthropic grounds is not known, that opium was a baleful luxury to his army of coolies. Accordingly, he cut off the supply. The men began to flag and sicken at once, but to this he paid little attention, regarding it partly as shamming and partly the mere pangs of a morbid appetite. In less than a week, however, two-thirds were too weak to work; dysentery broke out, and before the frightened contractor could secure a new supply of opium, from a distant port, nearly half the poor wretches had died, and the remainder were months in recovering their strength. In some districts of India the drug is actually given to horses on long and severe rides by couriers, despatch-bearers, and others. The moderate user of opium, says the commission, seems to be as healthy, happy, and long-lived as the average abstainer. Its excessive use is, of course, injurious, as also is that of tea or pie, but such excess is said to be exceptional. As to the mechanism of the alimentary service of these food-narcotics, we are completely in the dark; but then so we are also as to their medicinal effects. The facts seem, however, to be unquestionable. We have the unanimous testimony of humanity to both. There is not a nation upon the globe of whose regular dietary one or more of them do not form a part. This fact alone establishes for the naturalist a high presumption in favor of their usefulness. He, at least, cannot bring himself to believe that all men are fools. "What all men in all times have believed" is considered a weighty argument now, even in theology.

A Recent Action of the Illinois State Board of Health is worthy of mention. At the June meeting a resolution was passed requiring all medical students in the State of Illinois to pass their entrance-examination before the Faculty of the State University. This is following out the plan of the Regents of the University of the State of New York. It will relieve the medical colleges of Chicago of the necessity of holding these examinations, and it will place them all upon the same footing.

During the past few years a number of new schools of medicine have come into the field and made competition for the medical students in Chicago more severe. The preliminary examination has become a crucial point with many of them. Minnesota, Wisconsin, Iowa, and Missouri are favorably situated to follow New York and Illinois in this movement.

At the last meeting of the Association of American Medical Colleges a resolution was introduced which will be acted upon at the coming meeting in Atlanta, requiring all colleges members of this Association to place their entrance-examinations outside of their own control. Thus we see that the Boards of Health are seconding the efforts of medical educators in relieving the colleges of the only stigma that remains upon them.

It is one step further in the same direction to place the examinations of all candidates for the degree of Doctor of Medicine, and for the licence to practise medicine, in the hands of the Faculty of the State University. This examination must become the rule both for the protection of the public and for the self-respect of the schools.

Sexual Physiology in the Girls' High School.—In the Girl's High School of Philadelphia physiology is one of the regular studies, and yet in this study the questions of sex and generation are practically ignored. It seems that those in authority (not the teachers) are afraid the young women may learn something that they ought to know. Where is a girl to derive her knowledge of these subjects, we ask? Her mother will not tell her, or may be as incapable of instructing her in the functions of the sexual organs as she is incapable of teaching her the functions of the heart and brain. In civilized communities natural instincts are not proper or trustworthy guides, and consequently the only teachers that remain are companions who have derived their knowledge in some haphazard and dangerous way, or from sensational and unreliable literature. Three or four lectures on comparative embryology would suffice to give the students the requisite knowledge, and a lecture on the hygiene of the sexual functions might be added. These girls, who are to be the future mothers of the community, cannot know too much about themselves, especially if the knowledge imparted is of the right kind.

Commercial Hydrogen Dioxid.—In the current number of the *American Journal of Pharmacy* is published a note on the strength of commercial samples of hydrogen dioxid. Twenty-five samples were tested, showing an average strength of 9.94 volumes, the highest being 10.37, the lowest 9.03 volumes. Unfortunately, the samples are designated only by numbers, no clue being given as to the manufacturers. Analytic statements of this character are of little professional value. The reports should state the brands tested, the condition under which samples were obtained, and should indicate, at least briefly, the method of analysis.

Removal of the Editorial Office of the Medical and Surgical Reporter.—We learn with regret that our most esteemed contemporary, the *Medical and Surgical Reporter*, in order to be nearer the printing-office of its new publisher, has removed its editorial offices to New York. We are sorry that business reasons should force it to exchange the medical atmosphere of its lifelong home for one of such uncongenial surroundings. It is indeed true that the footings of our clearing-house transactions do not equal those of our self-complaisant sister city.

REVIEWS.

INDIGESTION. AN INTRODUCTION TO THE STUDY OF DISEASES OF THE STOMACH. By GEORGE HERSCHELL, M.D. Lond. Second edition. New York: G. P. Putnam's Sons. London: Baillière, Tindall & Cox, 1895.

HERETOFORE no English writer has attempted to describe stomach diseases from the modern standpoint. In making the attempt our author necessarily has departed widely from the course adopted in the former edition. In some respects the arrangement of subjects is admirable, and admits of greater simplicity and brevity than is usual. It is to be regretted that the author has not taken full advantage of his plan. Briefly stated, there are described, 1st, normal digestion; 2d, disturbed

digestion; 3d, methods of examination; 4th, pathology of special diseases; 5th, treatment. Here is an opportunity for the avoidance of repetition, but unfortunately, under the heading "Interrogation of Patient," there is introduced a chapter of subjective symptoms, most confusing to the student, for whom the book purports to have been written. It appears to be a concession to more antiquated ideas of investigation, proper enough in its place, perhaps, but too conspicuous here.

The modern methods of examination are for the most part clearly stated, and are sufficiently complete for a book of this character. The author's ideas of treatment are acceptable, and much good must be accomplished by spreading his doctrine in Great Britain.

It is unfortunate that in the interests of brevity the element of style has been so much disregarded, and, aside from this criterion, it must be admitted that the diction is imperfect. For instance, it is said (p. 176): "Obstruction in the duodenum may be either a neoplasm, a cicatricial contraction, or due to a flexion." Again (p. 177): "Neurasthenia and many other symptoms are caused by the absorption of toxins from the dilated stomach." Again (p. 176): "The stomach being unable to ever absolutely empty itself." Nearly every page exhibits similar experiments in construction. In the next edition it is hoped that the faults, which, by the way, are more conspicuous than harmful, will be eliminated, and there will remain a good short work on the stomach.

The author recognizes the important etiologic influence of reflex irritation in the production of gastric neuroses, and justly commends the teachings of an American physician in this connection. A writer who shall assign full value to ametropia and heterophoria in the etiology of gastric disorders will become as useful as he is uncommon.

THE CARE OF THE BABY: A MANUAL FOR MOTHERS AND NURSES, CONTAINING PRACTICAL DIRECTIONS FOR THE MANAGEMENT OF INFANCY AND CHILDHOOD IN HEALTH AND IN DISEASE. By J. P. CROZER GRIFFITH, M.D., Clinical Professor of Diseases of Children in the Hospital of the University of Pennsylvania; Professor of Clinical Medicine in the Philadelphia Polyclinic and School for Graduates in Medicine; Physician to the Children's Hospital, to the Methodist Episcopal Hospital, and to St. Agnes's Hospital, Philadelphia; Member of the American Pediatric Society and of the Association of American Physicians. Philadelphia: W. B. Saunders, 1895.

THIS book, of three-hundred-and-ninety-two pages, is, as its title indicates, designed as a guide to mothers and nurses in the care and bringing up of infants and children. That such a guide is essential, particularly to a mother with her firstborn, is evidenced by the gross ignorance of the simplest details in regard to the care of the child, and by the many popular fallacies in regard to infancy that have been handed down from time immemorial by those who profess to be knowing and skilful nurses of babies; and this is so not only among the poorer classes, but even among the well-to-do. Everyone who has seen much of children cannot but be struck by the joy with which a kind(?) neighbor imparts her ignorance to an anxious, young, and inexperienced mother, not only needlessly alarming the latter, but also doing absolute harm by her ignorant counsel. It is certainly of advantage to both mother and child that such a book as that before us should be available.

The author devotes about a dozen pages to some useful information to the mother in regard to her life prior to delivery, and as to the preparations necessary for confinement. The newborn baby is then described in sufficient detail as regards its superficial anatomy and its physiology. The manner and rate of growth and development of the teeth are fully dealt with in the succeeding chapter. Chapters on the toilet and the clothing suitable for the different ages are followed by an extremely good chapter on the diet. In the latter the author's views are not far different from those of other writers upon the selection of children's diet. He decidedly prefers the use of soda-solution to that of lime-water as an alkalinizing medium in the use of cow's milk. Sleep, exercise, and training, the baby's various nurses, and the baby's rooms finish the portion of the book devoted to the baby in health. The chapter on the sick baby occupies most of the rest of the volume. In it the author describes the features of disease, the management of the sick baby, and the disorders of childhood. The author is to be congratulated upon having written this chapter with such judgment that the mother will be aided in her ability to watch over her child properly without thinking herself capable of conducting the medical treatment through an illness. This, probably the most difficult chapter to write well, is one of the best in the book.

In the appendix are given minute directions for preparing various articles of diet, descriptions of the different forms of local and general baths, directions for making some of the principal poultices and plasters, formulæ of different lotions and powders for external use, formulæ for a few simple domestic remedies for use in emergencies, and some miscellaneous directions in regard to massage and the administration of drugs.

The writing of such a book must be difficult chiefly from the necessity for discrimination in regard to the extent to which it is judicious to enter into medical details. To us it seems that Dr. Griffith has well accomplished his work in this respect, neither making too light of the appearances of illness nor unnecessarily causing alarm by mention of possible serious consequences.

PATHOLOGY AND TREATMENT OF DISEASES OF THE SKIN. By MORIZ KAPOSI, Professor of Dermatology and Syphilis in the Vienna University. Translation of the last German edition, under the supervision of JAMES C. JOHNSTON, M.D. Pp. 684. New York: William Wood & Co., 1895.

THE author of this work is so well known to readers of German interested in diseases of the skin that an introduction is unnecessary. Professor Kaposi (the worthy successor to Hebra the elder, in the chair of dermatology in the University of Vienna) presents in this work the principles and practice of dermatology as recognized by the Vienna School of Medicine, of which he is now the chief exponent. The subject-matter is in the form of lectures, and is, therefore, didactic. Pathology and pathologic anatomy receive much attention.

As is well known, the Vienna school attaches but little importance to internal remedies in the treatment of cutaneous diseases, and the American reader in perusing this book will look in vain for advice upon the use of the many internal remedies constantly employed by physicians in this country in treating such diseases as eczema and psoriasis.

The distinguished author is a Viennese, and not a cosmopolitan, in his views. He pictures graphically diseases of the skin as they are met with in Austria, but accords scanty notice to the work that has been done in other countries during the last decade. Nevertheless, the book is one of the great works of the period, and is full of valuable information, the fruit of a lifelong and abundant experience by an unusually accurate and keen observer. We are, therefore, pleased to see the work translated into English.

The translation has been done freely rather than literally, with here and there the omission of a sentence or a paragraph, doubtless with the view of condensation. We are somewhat in doubt as to whether Dr. Johnston is the translator or not, inasmuch as on the title-page it is stated that the translation has been done under his supervision. In one chapter the term *knötchen* is translated nodule, instead of papule, as it should be. In conclusion, we may say that the book should be in the library of every physician interested in dermatology.

NEWS ITEM.

For the James E. Reeves Fund we have received from Drs. E. B. Doolittle, 50 cents; A. Cornish, $1; G. W. H. Kemper, $1; H. M. Haskell, 50 cents. We quote the following paragraph from Dr. Haskell's letter:

"Surely the professional conscience, and especially the journalistic, is not so seared as to turn a deaf ear to this call. There ought to be from 50,000 to 100,000 copies sold, and the balance kept as a sinking or trust fund to defend similar cases in the future."

BOOKS AND PAMPHLETS RECEIVED.

Inebriety or Narcomania: its Etiology, Pathology, Treatment, and Jurisprudence. By Norman Kerr, M.D., F.L.S. Third edition. New York: J. Selwin Tait & Sons, 1894.

Ripening of Immature Cataract by Direct Trituration. By Boerne Bettman, M.D. Reprinted from the Annals of Ophthalmology and Otology, Vol. IV, No. 1, 1895.

On the Physiological Action of Antitoxin in Diphtheria. By G. P. Hackenberg, M.D. Reprinted from the American Practitioner and News, 1895.

Ein Beitrag zur Aetiologie der contraren Sexualempfindung. Von Dr. Freiherrn v. Schrenck-Notzing. Beilage zur Wiener klinischen Rundschau, 1895, No. 8.

The Possibility of Obtaining Marked Improvement in the Treatment of Diseases and Supposed Deaf-mutism by Acoustic Gymnastics. A System of Vocal Training of the Auditory Nerve, as Advocated by Professor Urbanschitsch, of Vienna. By Dr. M. A. Goldstein. Reprinted from the Archives of Otology, 1895.

Hyperpyrexia in Broncho-pneumonia; Infantile Scurvy; Meningocele. By Edwin E. Graham, M.D. Reprinted from the Internation Clinics, Vol. IV, Fourth Series

A Case of Neurotic Edema. By Edwin E. Graham, M.D. Reprinted from the Annals of Gynecology and Pediatry, 1894.

Nervous Diseases in Early Syphilis. By G. Frank Lydston, M.D. Reprinted from the Journal of the American Medical Association, 1895.

Tetany in America, with a Report of Five Cases. By J. P. Crozer Griffith, M.D. Reprinted from the American Journal of the Medical Sciences, 1895.

Sixty-fifth Annual Report of the Inspectors of the State Penitentiary for the Eastern District of Pennsylvania. Philadelphia, 1894.

Forms of Paralysis in Children. By J. P. Crozer Griffith, M.D. Reprinted from the International Medical Magazine, 1895.

Medical Gynecology. A Treatise on the Diseases of Women from the Standpoint of the Physician. By Alexander J. C. Skene, M.D. With illustrations. New York: D. Appleton & Co., 1895.

Appendicitis. By George W. Gay, M.D. Reprinted from the Boston Medical and Surgical Journal, 1895.

A Case of Lesion of the Thalamus. Death from Intestinal Hemorrhage. By Wharton Sinkler, M.D. Reprinted from the Journal of Nervous and Mental Disease, 1894.

Sporadic Cretinism, and its Treatment by Thyroid Extract. By Wharton Sinkler, M.D. Reprinted from the International Medical Magazine, 1894.

Pigmentum Chloralis Antisepticum. By Dr. John Broom. Read before the British Medical Association, August, 1894.

Left Hemiplegia. By J. T. Eskridge, M.D., with Remarks by Frederick Peterson, M.D. Reprinted from the New York Medical Journal, 1895.

A Study of Erysipelas. By Julius Selva, M.D. Reprinted from the New York Medical Journal, 1894.

Free Hydrochloric Acid. Is its Absence from the Stomach a Sign of Cancer? By Richard B. Faulkner, M.D. Reprinted from the Journal of the American Medical Association, 1895.

Report of a Case of Pathological Separation of the Lower Epiphysis of the Femur. By A. H. Meisenach, M.D. Reprinted from the Annals of Surgery, 1895.

The Abnormalities of Ocular Balance: their Nature, Etiology, Conservative Management, and Operative Treatment. A Clinical Study. By S. D. Risley, M.D. Reprinted from the University Medical Magazine, 1895.

The External and Internal Use of Guaiacol, with Brief Reports of Cases. By J. M. Anders, M.D. Reprinted from the Therapeutic Gazette, 1895.

A Report of Thirteen Cases of Ataxia in Adults with Hereditary History. By Irwin H. Neff, M.D. Reprinted from the American Journal of Insanity, 1895.

An Epidemic of Typhoid Fever at Bayhead, N. J., from Direct Infection of a Milk-supply. By W. H. Katzenbach, M.D. Reprinted from the Medical Record, 1895.

Demonstration of Skulls Showing the Effects of Cretinism on the Shape of the Nasal Chambers. By Harrison Allen, M.D. Reprinted from the New York Medical Journal, 1895.

Morphology as a Factor in the Study of Disease. By Harrison Allen, M.D. Reprinted from the Transactions of the Congress of American Physicians and Surgeons, 1894.

The Filtration of Public Water-supplies. By Henry Leffmann, M.D. Reprinted from the Copyrighted Proceedings of the Engineers' Club of Philadelphia, 1895.

Bicycling for Women from the Standpoint of the Gynecologist. By Robert L. Dickinson, M.D. Reprinted from the American Journal of Obstetrics, 1895.

Purulent Fibro-myomata of the Uterus, and Professor Vulliet's Operation for their Extraction. By Charles Greene Cumston, B.M.S., M.D. Reprinted from the Annals of Gynecology and Pediatry, 1895.

Thirty-fourth Annual Report of the Board of Managers of the Woman's Hospital of Philadelphia. January, 1895.

Thirteenth Annual Report of the Children's Aid Society of Pennsylvania, 1894. 321 South Twelfth Street, Philadelphia.

Some Remarks on Skiascopy, or the Shadow-test. By J. Thorington, M.D. Reprinted from the Annals of Ophthalmology and Otology, vol. iv, No. 1, 1895.

The Influence of the Eye on Character and Career. By Justin L. Barnes, B.S., M.D. Reprinted from the New York Medical Journal, 1895.

Pyometra in a Cat. By T. S. Cullen, M.B. Reprinted from the American Veterinary Review, 1894.

VOL. LXVII. SATURDAY, AUGUST 3, 1895. No. 5.

ORIGINAL ARTICLES.

THE OCULAR SYMPTOMS OF LOCOMOTOR ATAXIA.[1]

BY WILLIAM E. BRUNER, A.M., M.D.,

OF CLEVELAND, OHIO;

CLINICAL ASSISTANT IN OPHTHALMOLOGY, DISPENSARY OF THE WESTERN RESERVE MEDICAL COLLEGE, AND ASSISTANT IN CHARGE OF EYE CLINIC, CHARITY HOSPITAL.

VERY important in the diagnosis of tabes dorsalis, and especially in the early stages of the disease, are the ocular symptoms. Every person in whom locomotor ataxia is suspected should be subjected to a careful examination of the eyes, and not rarely it is the oculist whom the patient with developing posterior sclerosis first consults, and upon whom the responsibility rests of first detecting the oncoming disease in perhaps its very earliest stage, when, if at any time, it may be possible to check its progress. The ocular symptoms naturally arrange themselves into three groups: those pertaining to the internal muscles, especially the iris; those concerned with the external eye-muscles; and the changes in the optic nerve, or optic atrophy.

The affections of the internal muscles reveal themselves chiefly in pupillary changes, and these are numerous. The most important are: 1. Reflex iridoplegia. 2. Absolute iridoplegia. 3. Myosis. 4. Inequality of the pupils.

We should add to the pupillary symptoms mydriasis, one form of which would indicate irritation of the cilio-spinal center, and would be analogous to the increased knee-jerk found by Weiss and some others at the beginning of tabes. Instead of spastic mydriasis we may have another form—paralytic mydriasis.[2] Gowers states that the pupils may be even larger than normal, and then, he adds, the skin-reflex can be obtained, though the light-reflex cannot. Eulenburg,[3] among 64 cases, noted mydriasis in 9, myosis in 28, and states that the simultaneous occurrence of myosis and mydriasis occurs only in the late stages of the disease. Seguin found the mydriasis to be symmetric, differing in this respect from Müller[4] and Schmeichler. Hutchinson[5] reports a case in which monocular paralytic mydriasis preceded other ataxic symptoms by three years.

Though not so characteristic as the other changes, pupillary inequality is, according to Schmeichler,[1] the most frequent, while reflex iridoplegia is next in frequency. "Each of these symptoms," he says, "when found in an individual justifies the physician in inquiring for tabes." Jessup[2] says that inequality is often found, and Berger found it in 27.6 per cent. of his cases.

The myosis frequently spoken of as spinal myosis is an important sign of disease of the posterior columns of the cord. The only other disease in which it occurs as frequently is progressive paralysis of the insane. In cases in which the cervical spinal cord is first attacked myosis occurs as a very early symptom. The pupils cannot be dilated *ad maximum* by the energetic use of a strong mydriatic.[3] A characteristic point in the myosis is the fact that the pupil dilated to medium width by atropin requires an unusually long time (frequently from four to five weeks) to become again as narrow as it was before the instillation of the mydriatic.[4] The myosis is due to paralysis of the cilio-spinal center. It is explained by one authority[5] by the fact that paralysis of this center, which sends the vasomotor fibers to the bloodvessels of the iris, allows these vessels to become relaxed and consequently filled with blood, and hence the small pupil results. The longer this condition remains the more slowly will passive dilatation occur. The very minute pupil sometimes seen is, according to Noyes,[6] probably due to secondary contraction of the sphincter pupillæ.

Total iridoplegia, the reaction in accommodation as well as to light being lost, but accomodation itself remaining intact, is sometimes seen, but the most characteristic of all the pupillary changes is reflex iridoplegia, the pupil not responding to light, but reacting in accommodation. This condition is now familiarly known, in honor of the man who discovered it and brought it to the notice of the profession, as the Argyll-Robertson pupil.[7] It is explained as being due to paralysis of the cilio-spinal nerves, which were then regarded as the nerves supplying the sphincter iridis, but is now believed

to be due to disease at some distance from the spinal cord, namely, in Meynert's[1] fibers, which connect the corpora quadrigemina with the nuclei of the third nerve. Disease in these fibers may exist by continuity with disease of the cord, and in fact the close relationship between the optic atrophy and the sclerosis of the posterior columns is similarly explained, as Stilling[2] has found fibers passing directly from the optic tract into the crus cerebri, and both he and Edinger assert that this bundle of fibers makes its way through the crus to the pons varolii, and thence to the posterior column of the cord. Noyes[3] says that the Argyll-Robertson pupil may be due to disease of the fibers from the optic tract to the pons varolii, while Turner[4] holds the opinion that it is due to a lesion of the fibers connecting the optic tract and the pupillary nucleus—a statement that accords with that made by Swanzy, though less definite. Mauthner's[5] explanation is that the fibers for the pupillary light-reflex, lying in the wall of the third ventricle, suffer from a chronic ependymitis and a consequent sclerosis, an opinion with which Berger[6] agrees. Kahler, Mendel, and Oppenheim found the oculomotor nucleus intact, with absence of the light-reaction. "Hence," says Knies,[7] "the lesion must be sought in the centripetal fibers to the motor oculi nucleus or in their origin, unless the condition is due to a toxemia." Schmeichler,[8] however, believes that we cannot attribute this reflex iridoplegia to any direct anatomic basis, but that we must assign it to the "generally reduced irritability of the brain due to a morbid process." The whole nervous system, he contends, is inclined to sclerosis, which is, however, most marked in the posterior columns and optic nerves. It is proper, he thinks, to speak of a "diminution of nervous excitability in tabetics, which, while too slight to produce coarse functional disturbances, suffices to disturb the sensitive reflex mechanism of the pupil."

Usually in association with the Argyll-Robertson pupil we find, as was first observed by Erb, that the iris fails to dilate upon painful stimulation of the skin, especially of the skin of the neck. Reflex iridoplegia is sometimes accompanied by mydriasis and occasionally by paralysis of accommodation, but most often by myosis, and not infrequently there is slight irregularity in the outline of the pupil. Eventually the iris often fails to react in accommodation as well as to light. Sometimes we find decided torpor or sluggishness of the iris, but no paralysis; in fact, if we could trace the pupillary condition from the beginning, we should often find this torpor, then loss of reaction to light, then to irritation of the skin, and finally total iridoplegia.

I have said that reflex iridoplegia is the most characteristic of the pupillary changes. Wood says that it probably is pathognomonic of degeneration of the upper spinal cord, including the medulla, and that it occurs also in progressive paralysis of the insane; and Dana also says that it is found practically only in these two conditions. It occurs probably in some cases of nuclear disease,[1] and possibly in disseminated sclerosis; but so rarely is it found in any other condition that its presence alone, says Hansell,[2] would almost warrant the assumption of a commencing posterior sclerosis.

The pupil may rarely be unaffected in tabes. Gowers states that the reflex action to light is lost in more than five-sixths of all cases, and Berger,[3] in a series of 109 cases, found good pupillary reaction in only four (3.7 per cent.), and only in one case with ataxia well marked. Vincent[4] found the Argyll-Robertson pupil 47 times in 50 patients. On the other hand, Nettleship[5] says: "We do not yet know how often it may occur in healthy persons, or without eventual spinal disease. It certainly has comparatively little significance in old persons." Uhthoff[6] found it in a case of carbon-disulphid poisoning. Its loss may be due to preceding syphilis. Gowers[7] reports having seen several cases of loss of light-reflex in syphilitic patients without disease of the spinal cord, and his practical rule is that, apart from general paralysis of the insane, reflex iridoplegia always indicates either syphilis or tabes, and not infrequently both. Erb has described a similar case. So important, however, is this symptom that Spitzka[8] says it "may be regarded as a rule in neuro-pathology that whenever reflex iridoplegia is at any time accompanied by other acute motor disturbance, it is either of spinal origin, or in exceptional cases due to disease of the pons varolii." It is one of the earliest signs of developing tabes. "It may be assumed with safety," says Spitzka, "that in 99 out of 100 cases both the

inability of the pupil to respond to light and the absence of the knee-jerk will be found long before ataxia is developed," though he states that the "loss of co-ordination and the reflex iridoplegia are the most important of the exact prodromal signs." In fact, he declares that one or both of these must be present to justify the diagnosis of incipient tabes; "not even the absence of the knee-jerk ranks as high as these two signs." When present this reflex iridoplegia is permanent and unvarying, and yet even in this regard there are rare exceptions, as Spitzka[1] has reported two cases in which this symptom disappeared, to reappear in two months in one case, and in eight months in the other case.

Berger[2] reports two cases in which this condition was unilateral, and Gowers one such case. Hansell[3] reports a case in which were found anisocoria (inequality of the pupils), unilateral Argyll-Robertson pupil, limited color-field, partial loss of knee-jerk, and fleeting pains in the feet. Recently I myself had a similar case under observation.

Paralysis of accommodation is occasionally met with as an early symptom. Galezowski has reported several such cases, and Berger[4] reports two without paralysis of the sphincter, but with reflex iridoplegia. In the latter stages of the disease this paralysis is more frequent, and Berger reports 23 cases, in "only one-third of which was the paralysis of accommodation accompanied by mydriasis."

The tabetic affections of the external eye-muscles may be divided into two groups, those occurring early in the disease and frequently transient, and those belonging to the later stages of the disease, and more often permanent, though either may occur at any stage.

In regard to the relative frequency of the muscles or nerves affected, the third nerve is the most often paralyzed, the sixth less frequently, and the fourth only exceptionally; but of individual muscles, the external rectus is most frequently affected, while ptosis from paralysis of the levator palpebræ superioris and paralysis of the internal rectus (causing external squint) are next in frequency. Several muscles may be involved, or we may have an "associated paralysis," as loss of convergence with loss of accommodation, although the internal recti act well under other conditions; or a progressive ophthalmoplegia or complete ophthalmoplegia externa. Buzzard[5] reports two cases of ophthalmoplegia externa in tabes, while Hutchinson,[6] in commenting upon six cases of this condition, says: "There can be no doubt that ophthalmoplegia externa is sometimes a part of the general malady known as locomotor ataxia, especially when that disease is due to syphilis."

As the result of paralysis of an external ocular muscle diplopia arises, which is homonymous when internal squint occurs, crossed when there is external squint, vertical if an elevator or depressor is affected, or there may be a combination of the last with either of the former.

Swanzy[1] declares that in "the premonitory stages of tabes dorsalis, ephemeral partial paralysis, affecting now one and again another of the orbital muscles, may sometimes be observed;" and Jeffries[2] says: "In tabes, as has long been known, there has been frequently a history of transitory diplopia during the prodromal period. The origin of these fugacious paralyses is not known, but their significance, when combined with previous syphilitic infection, is gravely suggestive of tabes to follow." All authorities agree that diplopia is not an infrequent early symptom, though they differ somewhat in regard to the percentage of cases showing this condition. Spitzka,[3] for example, found it in 58 out of 81 patients recorded, and Berger[4] in 38 per cent. of his cases, while Erb[5] assigns 27 per cent. of eye-paralyses to tabes, and Moli[6] 39.6 per cent. Sometimes the paralysis comes on gradually and is not noticed by the patient, but more often it causes very annoying diplopia. This may be the first symptom to attract the patient's attention, as in a case that I saw some time ago, in which, however, the patient, upon examination, also exhibited loss of knee-jerk, some ataxia, and slight pains, with the light-reaction of the pupils preserved, but sluggish. Osler[7] says: "The early ocular palsies are of the greatest importance. A squint, ptosis, or Argyll-Robertson pupil may be the *first* symptom, and may exist with the loss only of the knee-jerk." Nettleship[8] also states that tabes may be preceded by paralysis of one or more muscles, and that "there may be for years nothing else to attract attention." Cromwell[9] states that in tabes dorsalis the paralysis (of the eye-muscle) often precedes the other symptoms some months, and, at times, years." This condition occurs very rarely, if at all, in any other form of spinal disease. The importance of this as an early symptom may be inferred from the declaration of Schmeichler[10] that "if a pupillary disturb-

[10] Op. cit.

ance is added we are compelled to suspect tabes, and if lancinating pains appear the diagnosis of posterior spinal sclerosis may be accurately made." Pearce[1] reports a case, in the service of S. Weir Mitchell, of rapid onset, with sudden diplopia, due to paralysis of both external recti, as the first symptom. Hansell[2] cites one in which diplopia was the first symptom observed by the patient, and examination showed an Argyll-Robertson pupil, with the optic nerve normal, the knee-jerk exaggerated, and an absence of ataxia and of pains.

Hughlings Jackson found diplopia to be the first symptom in 6 out of 19 cases.

Ptosis, either unilateral or bilateral, occurs at times as an early symptom, and not infrequently is associated with paralysis of one or more muscles of the eyeball. Six months ago a patient consulted me because of a slight drooping of the upper lid of the right eye. He gave a history of syphilis, and upon close inquiry said that he had sharp pains at times in his legs, and occasionally had "bladder-trouble," with pain in the epigastrium, frequent micturition, and scanty urine. (Urine-analysis was negative.) Argyll-Robertson pupil was present, but there was no ataxia, and the knee-jerk was normal. Vision was normal, as were also the fields for form and color. Two months later the man returned, complaining of diplopia, which was found to be due to paresis of the right internal rectus. Despite the normal patellar tendon-reflex and the absence of ataxia, I am inclined to believe this a case of beginning tabes.

There seems to be a general impression among neurologists that paralyses of the eye-muscles, as manifested in ptosis, diplopia, and reflex iridoplegia, are more common in syphilitic patients.

Sachs,[3] in a paper read before the American Neurological Association in 1893, in attempting a differentiation of the cases of tabes due to an active syphilitic process, considered among that group those that exhibited complete loss of reflex contractility of one or both pupils, and ocular palsies. Spitzka,[4] on the other hand, states that the most obstinate and most severe diplopia he has met in a tabetic patient was in one in which syphilis was positively excluded, and Berger[5] says that he did not find luetic patients to be especially disposed to ocular palsy, although they do show a greater tendency to permanent paralysis and to multiple paralyses.

As to the anatomic cause of these paralyses, Berger says the lesion is nuclear; Förster that they are due to disease in the floor of the fourth ventricle; and Schmeichler[6] that they depend upon a sclerotic process in the vertebral artery, which furnishes the blood-supply to the nuclei of the eye-muscles, as well as the other basal ganglia, and also to the posterior columns of the cord, basing his opinion upon what Adamkiewicz has shown—that the path of tabetic sclerosis is determined by the course of these arterial vessels. Sachs,[1] in speaking along the same line, says that the chief cause of the degeneration of tabes is syphilis, which causes disease of the bloodvessels of the spinal cord, and altered states of the blood may be the prime cause of these changes in the bloodvessels.

Nystagmus has been observed, but is rare. It occurs chiefly with movements of the eyeballs, and is rarely persistent in continuous oscillation, as in multiple sclerosis. Rahlway[2] speaks of having observed it late in ataxia. Berger[3] reports seven cases, one of them unilateral, and Freyer[4] one case in which this was the only ocular symptom. Knies states that these rarer forms are perhaps always due to complications.

Another symptom that should not be ignored is epiphora, which usually is bilateral, but sometimes is unilateral. It is most probably due to weakness of the orbicularis, which may be explained, says de Schweinitz,[5] by the intimate relation of the oculo-facial group of muscles to the nucleus of the third nerve, which is frequently disturbed in tabes; for, according to Mendel,[6] the upper twigs of the facial nerve spring from a separate nucleus, which is in close relationship to the oculomotor.

According to Berger, however, hypersecretion is an important causative factor—a condition that has its analogy in the hyperidrosis of the face sometimes seen in tabes.

The relationship between optic atrophy and tabes is intimate. As regards its frequency authorities differ, ophthalmologists, for example, naturally reporting a higher percentage of cases with atrophy than neurologists. At the very least, 10 per cent. of the patients with locomotor ataxia exhibit more or less of optic atrophy; Gowers says one-sixth; Erb[7] 12 per cent.; Spitzka says if we include the lesser degrees of atrophy the percentage certainly is higher; Dana,[8] 10 per cent. in his experience; Moli, 13.5 per cent.; Uhthoff[9] (nervous clinic), 20 per cent.; Berger,[10] 51 in 109 cases (46.7 per cent.); Lofmarel,[3] 49 in 102 (48 per cent.);

[10] Op. cit., p. 455. [11] Quoted by Berger, op. cit., p. 455.

Cyon,[1] 60 in 203 (29.5 per cent.); Schmeichler,[2] from the cases seen in his eye-clinic, the medical clinic, and the Home for Incurables, 40 per cent. Buzzard[3] found it more frequently in disseminated sclerosis (43 per cent.), next in tabes (15.5 per cent.) and general paralysis of the insane. Calculating the frequency of spinal disease in cases of optic atrophy, Uhthoff,[4] in an analysis of 183 cases of optic atrophy from causes outside the eye, found it to be due to disease of the spinal cord in 59 cases (32 per cent.). Charcot believed that almost all cases of so-called simple atrophy ultimately present spinal symptoms; Gowers[5] about one-half; and Galezwoski about two-thirds.

Peltesohn[6] finds about 40 per cent. of the cases of non-neuritic progressive optic atrophy in Hirschberg's clinic to be associated with spinal or cerebro-spinal disease, and among 486 cases[7] he found 78 cases of tabes (15.7 per cent.). In a series of 76 consecutive cases of progressive atrophy Nettleship[8] reports decided spinal symptoms in 58, and of the remaining 18 several showed one or more symptoms that were probably of spinal origin. He is furthermore of the opinion that in the cases without signs of spinal disease, if they could be followed for a sufficient number of years, symptoms of such involvement would eventually appear.

Optic atrophy is usually an early, sometimes the initial, symptom of tabes. If the patient reaches the second stage without it, he will probably escape it altogether. There appears to be, as has been noted by many observers (Osler, Ferrier, Gowers, Buzzard), what might be termed an antagonism between the optic atrophy and the ataxia. When the former is an early and decided symptom ataxia is not likely to be marked, while in the cases in which the latter symptom is present the atrophy is rare or of very slight degree. Martin[9] claims that "when blindness from atrophy of the optic nerve occurs at an early period, especially when it runs a rapid course, a slow course of tabetic symptoms proper may be expected." Benedikt[10] is of the same opinion, and says that "it is a rule without exception, so far as my experience goes, that motor tabetic symptoms subside, however severe they may have been, as soon as atrophy of the optic nerve begins. The latter symptom, however, presents a very unfavorable prognosis." It may occur before any symptoms referable to the cord, as in a case mentioned by Gowers, in another by Bramwell,[1] and in seven cases by Berger.[2] Buzzard[3] records a case of not infrequent type, in which the only other symptom was loss of knee-jerk. The atrophy sometimes continues for years without any other symptoms.

Berger says that cases with ocular paralyses are slightly more disposed to atrophy, and the converse is also true. The left eye is oftener attacked than the right. "In general, paralyses of the external ocular muscles are found disproportionately oftener in cases showing optic atrophy than in cases uncomplicated with optic atrophy;" and "the cases with paralyses of the ocular muscles are more disposed to optic atrophy than the cases without paralyses." The change is usually more advanced in one eye than in the other, but it is rare to find complete atrophy in one eye and a normal nerve in the other. Schmeichler says that he has "never observed in tabes that one optic nerve was completely atrophic while the other eye enjoyed perfect vision."

The first result of a developing atrophy is in the color-perception, as shown by contraction of the color-fields when measured by the perimeter. Green, which excites the fibers least, is the first to be affected and to disappear; red follows, and the perception for blue is longest retained. The form-field then begins to suffer contraction and at the same time usually, or even a little earlier, vision begins to fail. Berger,[4] however, says that "contraction of the visual field precedes affection of the color-sense" and declares also that "no relation exists between the contraction of the visual field, the color-fields, the disturbances of central vision and of color-perception;" and with this opinion Leber[5] and Michel agree. My own experience does not accord with that of Berger, but agrees rather with that of Knies,[6] who holds that "central vision usually possesses a definite relation to the narrowing of the visual field, and is so much more impaired the more the boundaries of the field approach the point of fixation." Thus, optic atrophy is usually a gradual process, but occasionally it may be rapid. In the most rapid case recorded by Berger the atrophy took place in two months, and in the slowest in seventeen years. Hirschberg[7] reports a case in which vision was almost lost in eight weeks. It will usually progress to complete or almost complete blindness, with only light-perception remaining, but rarely it may advance to a certain stage and then stop. The contraction of the fields is usually concentric, though more marked at the temporal side (Förster) and

somewhat irregular. Rarely, however, a sector-like defect is met with, as in a case reported by Gowers[1] and in one by Uhthoff;[2] or one-half of the field is lost (Gowers,[3] Treitel,[4] and Berger[5]). Central loss of vision is even more rare, but a case of this kind is reported by Gowers[6], and Berry[7] also speaks of it. Bunge[8] reports a case, but does not go into details; Althaus[9] one case; and Berger two cases, one undoubted, with peripheral contraction first and scotoma later. So rare, indeed, is this last that Förster[10] says that if an atrophy begins with a central defect or central scotoma, it indicates that "we are not dealing with a tabetic atrophy."

Although it is true, as Stellwag[11] says, that vision is not "in direct proportion to the ophthalmoscopic appearances," or, as Knies[12] declares, that "there is often a disproportion in both directions between the visible atrophy of the nerve and the disturbance of vision," yet the condition of the veins can usually be readily recognized, even before vision begins to fail much. The essential ophthalmoscopic change is the discoloration of the papilla, which becomes of a grayish or bluish-white color. Mauthner[13] contends that the earliest and most important symptom in beginning atrophy is attenuation of the vessels, but Leber says that this is true only in neuritic atrophy and not in true primary atrophy. The vessels are about normal in size, except in the very late stage, when they often become narrowed. Schmeichler says that often one or more veins, usually the lower, are larger than normal and may be even twice the normal width.

The disc appears flat or slightly excavated, with its edges sharply defined, and is of an opaque bluish-gray color, while the dots of the *lamina cribrosa* become more visible, causing a "stippling," and the minute vessels of the disc are absent.

Before concluding I shall briefly report a case in which the ocular symptoms formed an important element in the diagnosis:

A. K., aged thirty-five years, was referred to me by Dr. H. S. Upson for examination. The patient had complete loss of knee-jerk; station was bad, and the gait was markedly ataxic; but there was no pain. The diagnosis lay between locomotor ataxia and multiple neuritis. Examination of the eyes showed pupils that responded readily to light and in accommodation; the external eye-muscles were normal; the optic nerves presented not the slightest indication of atrophy. Not only was vision normal after correction of the astigmatism, but the form-fields and, what was even more significant, the color-fields were perfectly normal. As a result of the eye-examination, multiple neuritis was suspected rather than tabes; and under treatment all the symptoms rapidly improved, the ataxia disappeared, and the knee-jerk returned to normal.

In conclusion, then, we should never lose sight of the importance of the ocular symptoms in all suspected cases of locomotor ataxia, and their value both in diagnosis and prognosis. Such examination should have regard to (1) the internal eye-muscles, as shown by the size of the pupils and their mode of response to light and accommodation; (2) the external eye-muscles (including the elevator of the upper lids), which so often are paralyzed, causing diplopia or ptosis; (3) the condition of the optic nerve, which in so large a percentage of cases undergoes more or less atrophy.

IS THE PHYSICIAN IN ANY WAY RESPONSIBLE FOR THE HIGH MORTALITY AMONG THE NEWLY BORN?[1]

BY M. A. CROCKETT, A.B., M.D.,
ASSISTANT GYNECOLOGIST TO THE BUFFALO GENERAL HOSPITAL, INSTRUCTOR IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO.

IN a recent address before the Society for the Protection of Children in France, the chairman, Dr. Rochard, stated that 250,000 infants perished annually, and that, in his opinion, 100,000 of these lives might be saved. The world knows that France is much alarmed over the fact that the nation is not increasing in numbers. Dr. Rochard points out that the country might be repopulated simply by diminishing this waste of infant-life. History furnishes several examples of the disastrous results following diminution of a nation's numerical strength. Infant-mortality might become a national question of great importance, and the State has a right to demand from the medical profession the causes that annually deprive her of so many lives.

In the first place, is it true that the mortality among the newly born is high? The term newly born is applied to the infant during the first month or six weeks of its existence. Eröss, taking sixteen large European cities as the basis for computation, states that 10 per cent. of children born alive die during the first four weeks of life. Oesterlen[2] states that the mortality of the first month makes up 42 per cent. of the deaths of the first year of life.

[1] Read before the Buffalo Medical Club, April, 1895.
[2] Handbuch der Med. Statistik, 1874.

Uffelmann[1] says that the mortality of the first four weeks is about equal to the mortality of the second and third years of life added together. One-quarter of all the deaths, up to the age of five years, occur in the first month of life. Smith[2] says that in England, where there is an accurate registration of births and deaths, among every 100 children born alive there are four or five deaths during the first month. He quotes a French author who places the mortality of the first month at 10 per cent.

In this country, owing to deficient registration of births, the statistics are unreliable, but all authorities agree that during the first month the mortality is very heavy. Think of the loss to a community represented by the enormous mortality of the first year of life, and then bear in mind that the first two weeks in the first month form the most critical time in this year and the very time during which the child is likely to be under a physician's observation. While there may be differences of opinion as to the exact mortality among the newly born, the facts show this mortality to be so great as to demand a positive answer to the question at the head of this paper.

Undoubtedly the mortality of the first month of life will always be high, for many of the deaths are unavoidable. There is a marked tendency, however, among physicians to ascribe to Divine Providence results brought about by their own ignorance and neglect. If it can be shown that a large number of the deaths among infants result from diseases that we usually consider preventable, we can no longer shield ourselves by casting the responsibility elswhere.

To learn anything definite about the newly born a large number of children must be studied. Eröss,[3] of Budapest, has recorded observations of 1000 infants. These children were examined twice a day and sections were performed upon all that died. Upon each visit the temperature was taken, with the striking result that in 430 of the children fever-temperatures were noted. Being surprised at this, Eröss used the thermometer among his private patients. He selected forty-two infants that were so situated as to receive the very best of care, and in twelve instances found fever present. He states that in most of these children the rise of temperature was the first sign of disturbance, and without the use of the thermometer his attention would not have been attracted to the infant. The lesson from this is obvious.

In 79 of the 430 feverish infants no cause for the elevation of temperature could be found; 220 presented evidences of disease of the cord or navel; 108 suffered from dyspepsia or intestinal catarrh, which, in many of the cases, was due to septic infection. Other diseases found among these 430 were bronchitis, pleuritis, peritonitis, meningitis, etc. This report of Eröss is full of valuable information, but the important facts for us are that 220 children showed disease of the cord and that many of the other diseases were those in which we recognize infection as a cause.

The same authority,[1] in another article, reports the results of observations upon 1000 children regarding diseases of the navel and the infections resulting; 680 infants presented some abnormality in the healing of the navel-wound; this abnormality, in many instances, being associated with serious disease of the organism.

It is now generally admitted that septic infection plays a most important *rôle* in the loss of life among the newly born. Epstein[2] says that much may be done to diminish the death-rate from pyo-septicemia in the newborn, which is too common even in private practice and under the most favorable surroundings. The most common entrance for septic matter is the umbilicus.

Fischl,[3] from a careful study of histories, sections, and bacteriology, in twenty-two newly born, comes to the following conclusions:

1. During the first few weeks sucklings are not uncommonly infected by septic microbes. The clinical and anatomic signs of this infection may be those of an acute or subacute gastro-enteritis, capillary bronchitis, or lobular pneumonia.

2. The grounds for classing these diseases in the group of septico-pyemias of the newborn is the close similarity, in histologic and bacteriologic conditions, between these affections and those diseases that, both clinically and anatomically, pass as septico-pyemic.

3. The histologic character of the organic changes consists in necrosis of cells and interstitial inflammation, with a tendency to hemorrhages. The microscopic changes in the mucous membrane of the gastro-intestinal canal may be slight or entirely wanting, even in cases in which the symptoms are most severe.

4. By means of culture-tests and inoculation-tests, streptococci and staphylococci are found in various organs, especially in the lungs.

5. The paths of infection are the navel-wound, with or without alterations in its healing, the food, and inspiration. The latter way is one of the most common and leads to the development of prominent pulmonary symptoms.

[1] Archiv für Gynäkologie, Bd. xli, H. 3.
[2] Jahrbuch für Kinderheilk.
[3] Zeitschrift für Heilkunde, Bd. xv, H. 1.

6. Acute dyspeptic diseases and genuine pneumonias are rare, and their prognosis is much more favorable than when gastro-intestinal or pulmonary symptoms accompany septic infection.

Tavel and Quervain[1] describe two cases of hemorrhage occurring in the newborn in which bacteriologic investigation of the blood was made. In the first case a purulent discharge from the umbilicus was noticed a few days after birth and multiple hemorrhages occurred ten days later. The post-mortem examination showed double pneumonia, with blood-stained fluid in the pleural cavities. The examination of the blood and organs revealed the presence of large numbers of streptococci. In the second case death took place from pneumonia. Hemorrhages were found in the pericardium, brain, and beneath the dura. Large numbers of staphylococci were present in the blood.

Escherich[2] says that trismus neonatorum is due to local infection of the umbilical wound. He reports three cases, in each of which there was septic inflammation of the navel, with peritonitis in one case and pneumonia in two.

Hirst[3] has reported the results of section in five children dying from septic infection through the umbilicus. In his opinion the average physician does not recognize the fact that septicemia of the newly born is common.

If the study of large numbers of newly born children and the opinions of distinguishd specialists carry any weight, we must recognize septic infection as an important factor in infant-mortality. It is also important to remember that the symptoms produced by this infection are varied and obscure.

Every newborn child has a physiologic wound. As the umbilicus is a recognized highway for infective bacteria, and may itself be the seat of septic inflammation, I make no apology for calling attention to this small area of the body.

Normally,[4] the amniotic sheath of the cord ends at a ring of skin upon the abdomen, but Wharton's jelly continues down to the subcutaneous and perivascular connective tissue. After the dead stump is cast off the umbilicus should heal by granulation, like any other wound. There are, however, certain reasons why infection is easy and the results serious: (1) the position of the navel-wound and its close relation to the peritoneum; (2) it contains the mouths of three large vessels; (3) its contact with moist, dead tissue.

There are certain anomalies that result in producing a large wound or disturb its healing. The most common of these anomalies are prolongation of the skin upward upon the cord, continuation of the amnion upon the abdomen, and a fleshy core projecting into Wharton's jelly.

Among a thousand infants Eröss found 22 per cent. suffering from navel-infection. Last year Doktor, of Budapest, showed how this percentage of infection could be lowered by more careful attention to the dressing of the cord. He studied 1200 children before he arrived at a satisfactory result. He found the following to be the best method: With a sterile ligature the cord is tied as close to the abdomen as possible, and with sterile scissors cut close to the ligature. Aseptic cotton is applied, and the dressing is not touched for three days. After the third day the dressing is changed every other day until the stump has dropped off. To insure rapid mummification the child is not bathed until the stump has separated, after which time there are daily bathing and dressing of navel. The care of the cord is carried out with the customary surgical details as to antisepsis, and is intrusted to the physician instead of the nurse; 230 children treated in this way showed a diminution of navel-infection from 22 per cent. to 3.46 per cent. Epstein condemns moist dressings and antiseptic powders. The navel-wound should be treated on ordinary surgical principles, namely, asepsis and avoidance of irritation. The physician has no right to leave this matter entirely to the nurse.

It is true that the traditions of a hundred years are violated by postponing the first bath for several days, but this causes no harm to the child. Doktor found a proportionately greater increase in weight and less skin-irritation in infants whose bathing was deferred. In this connection some observations of Liebreich[1] are interesting: "The *vernix caseosa*, which has hitherto been regarded as superfluous filth, cannot be taken as such. It is not a glycerin-fat, but consists of cholesterin-ether. This substance is germ-proof and air-proof. From this we conclude that Nature has given the child a natural protection against bacterial infection. The first bath should allow a reasonable amount of vernix to remain as a protection to the pores of the skin."

There does not seem to be much danger of hemorrhage in tying the cord so close to the abdomen, as in only one case in one-hundred did Doktor notice even slight oozing.

When the lying-in woman shows signs of sepsis, usually some one is to blame. During and after confinement we observe every antiseptic precaution, and, not content with this, on each visit we take the mother's pulse and temperature, recognizing the fact that forewarned is forearmed. Does the child usually receive so much attention from the physician? Its care is the province of the nurse,

[1] Centralblatt für Bakteriologie.

[3] THE MEDICAL NEWS, Jan. 9, 1892.
[4] Doktor: Archiv für Gynäkologie, Bd. xiv, H. 3.

[1] Medical Record, April 23, 1893.

perhaps an incapable one at that. Information about the child filters through the nurse or the mother to the physician. If the baby becomes ill enough to attract some one's attention, the doctor examines its condition, and perhaps discovers a disease already well advanced. The physician has never seen a case of septic infection in a newborn child for the same reason that the old practitioner never saw a ruptured perineum. Diseases of the newly born form a *terra incognita*, because the physician does not take the trouble to observe. Eröss found that out of 496,000 deaths of newly born children 45,000, or 9½ per cent., were ascribed to congenital weakness. What more need be said to support the charge of ignorance and neglect on the part of the medical profession regarding the newly born? Exact observation shows that very many children become ill during the first eight or ten days of life, and that the term congenital weakness is on a par with heart-failure.

The baby's life is held too cheaply, and too often the term "little stranger" expresses the feelings of the physician toward the newborn child. During pregnancy and confinement we are constantly reminded that we have charge of two lives, and after delivery the responsibility is in nowise diminished.

Instruction in our medical schools is lamentably deficient on diseases of the newly born. Can any recall many clinics devoted to this subject? In view of the high mortality among young babies are our schools not bound to furnish better instruction on this subject?

Long custom has intrusted the care of the newborn child almost entirely to the nurse. Cutting the cord and handing the child to the nurse are often a ceremony of great solemnity. To the mind of many a physician it represents the severance of his responsibility from the child and the formal transfer of his duties to another. There must be a reform in this matter. The first step toward saving these children's lives is the awakening of a proper appreciation regarding the physician's responsibilities. I need merely remind you of the brilliant results obtained from the proper *medical* care devoted to the healing of the umbilical wound alone.

I am aware that I have by no means exhausted this subject. It would be perfectly proper to go back to the time of labor and show how the lack or improper use of obstetric measures may result in bringing forth a child in poor condition to begin the battle of life. That part of the subject is large enough to furnish an essay by itself.

I will conclude by summing up some of the conclusions that seem to be justified by facts:

(1) The mortality of the newly born is both absolutely and relatively disgracefully high.

(2) Septic infection causes a part of this mortality, and is preventable.

(3) Asepsis should be observed about the newborn child. Dirty fingers or instruments should not be introduced into the child's mouth in cases of asphyxia. The child should not be allowed to ingest pus with its milk.

(4) The navel should be treated on modern surgical principles and have the personal supervision of the physician.

(5) The physician should take the child's temperature as well as that of the mother, bearing in mind that many of the septic diseases have an insidious approach, and that the importance of the thermometer cannot be overestimated.

(6) The navel-wound may be the path of infection without showing signs of local inflammation.

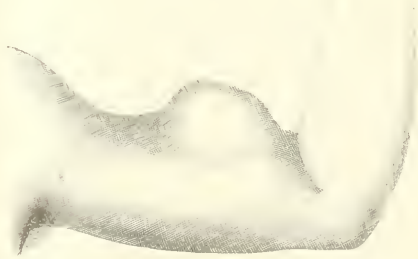
(7) Close observation of the newborn infant will teach the physician much and benefit the child greatly.

RUPTURE OF THE LONG HEAD OF THE BICEPS BRACHII MUSCLE ASSOCIATED WITH RHEUMATOID ARTHRITIS.[1]

By G. G. DAVIS, M.D., M.R.C.S. Eng.,
SURGEON TO THE GERMAN AND ST. JOSEPH'S HOSPITALS, PHILADELPHIA.

Recently two cases of rupture of the long head of the biceps muscle of the arm came under my notice which are of interest to physicians as well as to surgeons. Their histories are as follows:

The first case is in a laboring-man, aged thirty-seven years, who has had pain in the left hip and leg and right shoulder-joint for the past six weeks. The trouble in the hip and leg was painful and annoying, but has improved somewhat. The pain in the shoulder, on the contrary, has been very marked, and so disabled the patient as to cause him to apply for treatment. He has but little power in the arm.



Six days ago he noticed a lump on his right arm, which became more marked when the elbow was flexed. He states that he has no knowledge of having strained the arm in any way, and is not able to connect the appearance of the lump with any muscular effort. On examination the shoulder appears somewhat atrophied, and distinct grating can

[1] Read (and Patients Exhibited) before the College of Physicians of Philadelphia, May 1, 1895.

be felt and heard when the head of the humerus is rotated. On contracting the biceps muscle and flexing the elbow a marked lump occurs instead of the gentle swell of an intact muscle. This mass is evidently composed of that portion of the biceps attached to the long tendon. The unaffected portion of the muscle attached to the short tendon can readily be seen and felt to the inner side. The upper portion of the lump diminishes in a fusiform manner into the long tendon, which can be felt as a rounded cord disappearing in the axilla beneath the edge of the deltoid muscle. The shape of the enlargement varies according to the amount of the contraction of the muscle. The accompanying sketch shows its customary appearance. (See figure.)

The second case occurred in a blacksmith, aged sixty years. When twenty-five years of age he had an attack of rheumatism, which began in the feet and then involved the knees and hips. He was confined to bed for four or five weeks. At this time his arms were not affected. Nine months ago he was seized with pain in the right shoulder, which was so severe as to prevent him from sleeping and to deprive him of all use of the arm; so he stopped work, and has done none since. The pain lasted two months, and during this time there was nothing unusual seen about the arm. Four months ago, while under the care of Dr. Goodman, he noticed a lump on his right arm above the flexure of the elbow. This came without his knowledge, and did not supervene on any violent exertion. On examination the shoulder-muscles are seen to be atrophied, and the lump is evidently the long belly of the biceps muscle. Its upper portion can readily be felt to be prolonged into the long tendon, which disappears under the edge of the deltoid. The creaking and grating in the shoulder-joint, at first present, have now almost gone; the pain, though lessened, has not entirely disappeared. The power of the arm is much weakened, though the man can flex and extend it readily. Yesterday he drew my attention to his left knee, complaining of pain in it. Examination revealed a tumor, three-quarters of an inch in size, at the upper and outer border of the patella, which seems at times to move with the patella, but is evidently quite closely connected with it and in all probability is one of the fibro-cartilaginous growths that occur in the fibrous structures in the neighborhood of joints in those affected with rheumatoid arthritis.

Cases like these may come under the notice of either a physician or a surgeon. When the disease is somewhat obscure in its manifestations, particularly in its early stages and when several joints are affected, the patient, thinking he has rheumatism, is likely to apply for treatment to a physician; when, however, the local symptoms are marked, particularly if confined to a single joint, then he is likely, as did these two patients, to apply to a surgeon.

Rupture of one of the tendons of the biceps muscle is not particularly uncommon; four of such cases have come under my notice. Three were of the long tendon and one of the tendon of insertion at the bend of the elbow. The rupture is likely to occur either suddenly from violent exertion, or it may only be made known by the finding of an unusual lump at the seat of the muscular swell of the biceps in a patient suffering from disease of the shoulder-joint.

The tensile strength of healthy tendon is so great that it is my belief that true rupture is much rarer than is usually supposed, and that when a tendon does rupture it is very likely to have been diseased. Some cases that result from violent muscular contraction are, in reality, tearing loose of tendons from the muscular or bony tissue. One of the four cases I have seen was of that character. The patient was a young man, an athlete, who, while warding off a blow in sparring, felt a pain in the tendon of insertion of the biceps above the elbow, with loss of power in the arm. Dr. Beates, under whose care he was, stated that the belly of the muscle was drawn up, while the tendinous lower end could be distinctly felt with the fingers lying beneath the skin to the inner side of its normal position. By gentle manipulation the man was able to bring the lower end of the tendon opposite to the upper end, which was also gently pressed down into position, and by means of a suitable dressing the parts were retained in place. I saw the patient many months afterward, when union had occurred, and he had such good functional results that he ventured again to put on the gloves. The cause of the rupture in this patient undoubtedly lay in the pathologic condition of the muscle, because he was at the time of the injury muscle-bound, and had been for some time. Had the tendon itself been ruptured its lower piece would have been too short to be manipulated as it was. Rupture of tendons occurs in children with extreme rarity, their tissues not yet having begun to degenerate.

Bryant[1] details the case of a boy, aged eight years, with rupture of the biceps femoris tendon at the point of insertion into the fibula. Here again it is the point of junction of the tendon with the part to which it is attached that is involved, and not the tendon itself.

The cause of rupture of tendons is usually their being weakened by the disease variously known as rheumatoid arthritis, arthritis deformans, rheumatic gout, osteo-arthritis, etc. Robert Adams,[2] to whom we are indebted for our most accurate knowledge of this disease, describes the condition that it produces as follows: "Should we have an opportunity of examining the anatomical conditions of the tendons in and immediately around the shoulder-joint in any case in which the disease had existed in an

[1] Surgery, vol. ii.

[2] Rheumatoid Arthritis, 1873.

early stage, we shall find that these structures resemble tendons which had been for a long time macerating, and that they have their fibers widely separated from each other, as if they were about to resolve themselves into their primitive elements." (P. 97.) "As to the tendon of the biceps, except in those cases in which an opportunity is afforded to us of examining a shoulder-joint in which the disease is of an early stage, we usually observe that the whole of the intra-articular portion of it has been removed. The remains of the portion of the tendon of the biceps external to the capsule will be found to have contracted firm adhesions to the summit and edges of the bicipital groove." (P. 98.)

Rheumatoid arthritis is not a rapidly fatal disease, and just as Mr. Adams, as quoted, attributes absorption of the biceps tendon to a late stage of the disease, so likewise do his successors. That the tendon does rupture, and does become absorbed, is alluded to and well recognized by some writers, although many descriptions of this disease in medical works fail to make reference to this fact; but they universally associate it with more or less disorganization of the joint, and cause it to be considered as a late phenomenon in the progress of the affection. The contrary is true. It is likely to be a comparatively early symptom. Long before the marked change occurs that one sees in the familiar illustrations in the text-books the continuity of the tendon may be destroyed. In the first case reported here the disease had only been present for five weeks when the rupture occurred, and that, too, without the patient being cognizant of it, thus showing that the solution must have been nearly or quite complete. In the second case the disease had existed only five months when the rupture occurred. This is comparatively early, considering that the disease lasts for many years. In both patients the disorganization of the joint could not have been so very extensive, considering the slight restriction of motion that existed. In some cases the affection seems to involve the interior rather than the exterior of the joint, and the changes proceed outward. One can readily see why the biceps tendon, lying inside of the capsule, and only separated from the main joint-cavity by a synovial sheath, should be early affected and destroyed.

The line separating cases of rupture due to violence from those due mainly to disease is not always so sharply marked as the three cases detailed would seem to indicate. This is shown by the fourth case, which I saw some years ago. It occurred in a man advanced in years, and supervened on some violent exertion. He was, however, the subject of rheumatoid arthritis, and it is likely that in his case the tendon had been somewhat weakened by the disease and was partly absorbed, so that when the violent contraction of the biceps occurred it caused the weakened tendon to break. Is it not possible that the fibrous and tendinous insertion of muscles, particularly those inserted close to the articulations, may become affected by rheumatoid disease and so weakened as to cause their rupture without other appreciable signs of the disease? I am inclined to think so.

Bryant[1] says: "When one tendon breaks the other usually follows at a later date, thereby clearly indicating that they give way from some disease which affects their elasticity." Dr. J. Roberts Bryan informs me that he had a patient advanced in years who sustained a rupture of the quadriceps tendon just above one patella, which was followed several months later by rupture of the tendon on the opposite side at the same place; yet no other evidences of rheumatoid disease were present. If it is a fact that such cases are due to a weakening of the tendon by rheumatoid disease, it indicates the desirability of advising the patient to guard against any sudden, violent muscular effort, and may give us some clue to a correct prognosis as to the future course of the affection.

E. Pagenstecher[2] reports two cases of rupture of the biceps muscle, one occurring in a strong, muscular man while lifting a quarter of beef, and the other in an athlete. The histories are not complete enough to judge as to the causes favoring their occurrence.

ORIGINAL ADDRESS.

THE AMERICAN MEDICAL WOMAN.[3]

By FRANCES EMILY WHITE, M.D.,

of Philadelphia;

Professor of Physiology in the Woman's Medical College of Pennsylvania.

The present age is often called "the woman's age," and the woman of to-day is somewhat dubiously dubbed "the new woman." But, although the medical woman is a woman of to-day, she is not altogether new—not absolutely *fin de siècle*. Isolated accounts of doctors of medicine who were also women are scattered through the medical annals of all ages. Even Æsculapius (whose history is obscured by the mists of mythology) is said to have been followed by disciples of both sexes, and a college of physicians of both men and women existed in Egypt in the eleventh century B.C.

Women skilled in medicine also play conspicuous *rôles* in the great dramatic poems of the Greeks. Thus Homer, in describing one of the characters of the *Iliad* (Prof. Blaikie's translation), says:

> "A leech was she, and well she knew
> All herbs on ground that grew."

From the eleventh to the thirteenth century, A.D., the famous school of Salerno (said to form the bridge

[3] Address delivered to the graduating class of the Woman's Medical College, in the American Academy of Music, Philadelphia, May, 1895.

between ancient and modern medicine) boasted several renowned women-lecturers, and from that time to the present women have occasionally held chairs in various medical schools of Italy.

France, also, has accorded royal recognition to her distinguished daughters, Mesdames Boivin and Lachapelle—names familiar to all readers of medical literature.

But to the women of America, aided and abetted by justice-loving and generous American men, belong the distinction and the responsibility of inaugurating the first systematic effort toward the annexation of the medical field to the somewhat restricted territory recognized as lying within the legitimate sphere of woman.

During the colonial period, much of the medical practice in New England was in the hands of women whose sole qualifications are said to have been acquired in the rearing of large families, and there is no record of any serious conflict between the two kinds of activity. But as the practice of medicine became more scientific, there was an increasing tendency toward its restriction to those who had received a scientific training, and the practice of midwifery thus passed out of the "sphere of woman." But the promise and potency of the medical woman of to-day were latent in the conditions of the colonial age, and the Pilgrim mothers (who, as wittily pointed out by one of their remote sons, a citizen of Philadelphia, not only endured the common hardships of the period, but also endured the Pilgrim fathers), those dauntless daughters of an exigent situation, were the logical as well as chronological predecessors of women destined to share both the burdens and the privileges of American, medical, professional life.

In the history of the slow and difficult development of the untrained American midwife into the educated and legally qualified doctor of medicine the year 1849 must ever remain luminous—a red-letter year—the year in which Elizabeth Blackwell acquired the degree of Doctor of Medicine in an American school—the Medical College of Geneva, New York. In being the first woman in America to receive the medical degree, Elizabeth Blackwell unwittingly became the mother of us all—"the baby figure of the giant mass of things to come"—for tradition has it that the difficulties that she had encountered and the grave uncertainties that hung around the future of other women-aspirants for the medical degree first turned the minds of certain men and women of Philadelphia toward the unprecedented project of a medical school for women. Be this as it may (for the fruitful germ of this enterprise has been ascribed to more than one source), the coming event cast its shadow forward upon the retreating footsteps of this herald of a new evangel for women as she passed through Philadelphia on her way to Europe for further study; and the following year proved to be a second red-letter year in the history of the American medical woman—the year 1850—a date that adorns and dignifies the modest front of the Woman's Medical College of Pennsylvania.

There are two claimants to the distinction of being the first medical college for women in the world—the school in Philadelphia and a school in Boston, formerly "The New England Female Medical College." To this long-standing controversy I am able to contribute the following facts, obtained (in the case of the party of the other part) by myself from the archives of Massachusetts, which are preserved at the State House in Boston, guarded by the classic cod-fish (emblem of an early Massachusetts industry), and sheltered by the great gilded dome that accentuates Beacon Hill and dominates the consecrated precincts of the Common. The facts obtained from this unimpeachable source are as follows:

In the year 1848 there was organized in Boston a society of which the object was to provide women with the instruction necessary to qualify them for the practice of midwifery, which (as already explained) had long before passed into the "sphere of man." A school was opened and lectures on the subjects of midwifery and general medicine were provided. In April, 1850, this society was incorporated under the name of "The Female Medical Education Society" for the stated purpose of providing for the education of "midwives, nurses, and female physicians." But although the words "female physicians" occur in the act of incorporation, the charter did not grant the right either of appointing a medical faculty or of conferring the degree of Doctor of Medicine, and in 1856 a new charter was obtained by "an act to change the name of the Female Medical Education Society to the New England Female Medical College, and to reorganize the same." Section 4 of this act sets forth that "the trustees shall have power to appoint professors who shall constitute a medical faculty, and to confer the usual degree of Doctor of Medicine." The Medical Education Society thus became a medical college in 1856.

The charter of the Woman's Medical College of Pennsylvania was granted in March, 1850, and the first session of the school was opened the following October with a full faculty, organized for the instruction of women in the various departments of medicine, the corporation being authorized to appoint such a faculty and to confer the degree of Doctor of Medicine on graduates of the school. The college in Philadelphia thus antedates the college in Boston by more than six years, and even should the date of the incorporation of the society from which the Boston college sprung—April, 1850—be claimed as the date of the founding of the college (which seems to me wholly unjustifiable), the palm of priority must still be conceded to the college in Philadelphia chartered in March of the same year—a difference in its favor that might prove of immense importance in case, for example, some future millionaire should bequeath a fortune to the oldest medical college for women in the world. I would suggest, however, as a harmless precaution, that this future legal instrument contain the name of The Woman's Medical College of Pennsylvania in full!

Although our college had a less brilliant inauguration than the school in Boston (the Female Medical Education Society numbering more than 1500 members, many of them among the most influential citizens of New England), the subsequent history of the two institutions well illustrates the significant saying that "the blood of the martyrs was the seed of the church." The prolonged struggle of the college in Philadelphia and the lifelong devotion to its interests of a few women (two of whom were members both of the Board of Corporators and of the Faculty) have borne a rich harvest in the high standing accorded to the college by the profession at large, and in a world-wide reputation outside the profession.

The New England College, on the contrary, soon after the death of Mr. Samuel Gregory (the leading spirit both of the Society and of the Board of Trustees of the College), repudiated the broad scientific principles on which it had been established, and became merged in the School of Medicine of the Boston University—a homeopathic, coeducational school—the university itself (a *parvenu* among universities) being too little known to confer any standing on the college, which had forfeited its claim on the regular profession by selling its birthright for a mess of homeopathic pottage. In this matter the Quaker City, like the proverbial tortoise, has thus completely distanced its fleeter rival, and the persevering daughters of William Penn have quietly secured the precedence over their more demonstrative Puritan sisters.

In an admirable sketch of the practice of medicine by women, which appeared in the *International Review* for October, 1879, Dr. James R. Chadwick, of Boston, argues that, although the struggle of women to free themselves from the social fetters that have so long proved an obstacle to their pursuit of knowledge has of late been centered on the profession of medicine, the reason is not to be sought in any peculiar fitness of women for the practice of medicine, but rather in the fact that the movement has found support in certain sentiments common to all civilized communities—the sentiments of delicacy, fastidiousness, and modesty—which, Dr. Chadwick states, have been gaining in strength from the days of Queen Charlotte and the mother of Queen Victoria, both attended by midwives, while the court-physician waited in an ante-room in case of anything serious; as there are those now who, in trivial ailments, resort to a certain class of practitioners because their medicines are easy to take, but fall back on the regular profession, heroically ready to swallow anything, when the case becomes urgent.

The first impulse toward the medical education of women in this country may have been excited by the sentiment of propriety, for it appears to have been a reaction against what Mr. Gregory contemptuously styled "*man-midwifery*" that led to the formation, in Boston, of the society to which I have referred, in order evidently that the female obstetrician demanded by delicacy might acquire the education demanded by science; but to the argument from propriety was soon added another, founded on the excess of the female population—that distressing surplus, the despair of the political economist and the mockery of the moralist who regards it as the duty of every woman to marry—a surplus that in New England at that time amounted to 20,000 women, many of whom, it was urged, might find in the practice of midwifery a useful, honorable, and remunerative occupation—no small matter where 20,000 surplus, and hence superfluous, women were involved.

Whether or not the woman-doctor microbe may be traced to this source, it was about this time that the affection broke out—the germ finding a congenial *nidus* in the minds of a few women whose ambitions were not to be appeased by the sop offered by the Female Medical Education Society, however saturated with soothing suggestions of honorable usefulness and pecuniary competency; and these women demanded the opportunity of becoming fully educated as physicians. Now, although the invasion of the medical profession by women had been opposed by the profession in Europe from a conviction (probably sincere) of the intellectual incapacity of women, the mass of the profession in America never urged this point (for what reasons I will not undertake to explain), but based their objection (also probably sincere) on the totally different contention of impropriety[1]—a fatal mistake—for as the community gradually awoke to the necessity of regarding the question of propriety from the point of view of the woman-patient rather than of the woman-doctor, the argument from propriety veered to the other side of the question, and those who had urged it against the study of medicine by women were quite unexpectedly "hoist by their own petard!"—the supposed antitoxin only served to increase the virulence of the infection.

I would that something of the history and motives of all the women concerned in precipitating this agitation upon an innocent and unsuspecting profession might be known to every graduate and student of medicine present; but, among the number, the names of Elizabeth and Emily Blackwell and our own Ann Preston, of blessed memory, whose works do follow her, stand pre-eminent—for in this opening professional vista their prophetic souls seized on a more alluring anticipation than the mere preservation of propriety, however desirable this may have been deemed—and on a more blessed benefaction than a merely remunerative occupation for a few women; they descried for women an avenue of escape from the physical deterioration and intellectual inanition that ever lie in wait for the unoccupied—an outlet into an invigorating atmosphere of activity in which the possibilities of realizing the potential plenitude of her being as a member of the human hierarchy would be multiplied almost by infinity.[2]

That the social environment plays a conspicuous part in all phases of social progress is a commonplace of social science, but that a certain degree of adaptability on the part of the individual is also essential is an equally controlling principle in evolution.

The single element of a public sense of propriety (upon which Dr. Chadwick would put the entire *onus* of this movement) could never alone have led to the establishment of women in the medical profession. In order that a professional field may be successfully occupied by women, it must offer the following conditions:

1. The work required must come within the scope of their abilities—physical and mental.

2. It must afford opportunity for the exercise of the qualities generally described as "peculiarly feminine."

3. It must make such demands on both the physical and mental energies of women as shall serve to develop these energies in a satisfactory degree.

4. It must afford such pecuniary compensation as shall enable those who pursue it to devote their best efforts to the work, which must therefore be acceptable to the community.

That the medical profession fulfils these conditions in a high degree is proved by the fact that there are more than three-thousand women in this country alone engaged in the practice of medicine to-day—many times

[1] See article by Dr. Mary Jacobi in Woman's Work in America. New York: Hoyt & Co., 1891.

[2] See address by Elizabeth and Emily Blackwell, "Medicine as a Profession for Women," 1859; also "Reply to Manifesto of the Philadelphia County Medical Society," by Ann Preston, Medical and Surgical Reporter, Philadelphia, May 4, 1867.

as many as of those engaged in all the other professions put together.[1] But the conspicuous success of women in this as compared with other professions can only be attributed to a "peculiar fitness" for the work of the medical profession—to the lack, in other professions, of equal opportunities for the exercise of those qualities that have become specialized in women—the "peculiarly feminine" qualities—and Dr. Chadwick's reasoning evidently fails as an explanation of the woman-doctor.

Notwithstanding the existence in this country at the present time of from thirty-five to forty coeducational medical schools, the greater number of women now practising medicine here are graduates of schools exclusively for women, although the number of women's colleges of recognized position is only four. The coeducational schools include the medical departments of eleven universities—those of Michigan, Iowa, Minnesota, Colorado, California, Oregon, Buffalo, Syracuse, Boston, the District of Columbia, and the Johns Hopkins University of Baltimore.

The preference shown by women for schools attended exclusively by women might be variously interpreted as depending, perhaps, on geographic convenience, on favorable financial conditions, or (as the licence to practise as well as a medical education can be obtained only at a medical school) on less exacting educational requirements.

On the point of geographic convenience, I will cite the fact that of the nineteen women practising medicine in the State of Washington only one is a graduate of the Willamette University, in the neighboring State of Oregon. The geographic argument is thus disposed of.

The financial reason also fails as an explanation, as in the universities that receive State support the fees are notably less than in the colleges for women.

On the third point—that of educational requirements—investigation has disclosed several facts that bear on it:

1. That the required term of study in the colleges for women is longer than in most of the coeducational schools—our own college and the college of the New York Infirmary having been among the first in this country to lengthen the college-year and to increase the term of study to three and later to four years.

2. The results of competitive examinations for hospital-appointments, of examinations by State boards and for admission to State societies all show that women rank with the best when subjected to this test.

At the first examination held by the State Board of Maryland, in 1893, the highest percentage was made by the only woman presenting herself—a graduate of the Baltimore school for women; and in September last, at the State examination in New Jersey, a graduate of our own school took the highest rank. The records of competitive examinations for medical service in the Philadelphia and Polyclinic Hospitals in this city afford similar testimony. Thus the argument of less exacting educational requirements also breaks down as an explanation of the preference shown by women for their own exclusive schools.

[1] These figures were obtained from Polk's Medical Register of the United States for 1893. A recent census-report places the number at a little more than five-thousand.

The choice of a college is undoubtedly influenced by the clinical opportunities afforded in the localities concerned, and by the professional reputation of individual members of the various faculties. As to how much depends on the absence of male students—the degree of probability that inferior advantages and greater expense would be outweighed by this circumstance—must be left to the judgment of my hearers. A conclusive estimate of the influence of this factor could be reached only by a *consensus* of the views of those actually concerned—the students themselves; but in view of the general American confidence in the coeducational system (although it will be admitted that medical coeducation presents some exceptional features), taken in connection with the fact that most female students attend the clinics of the public hospitals where male students are also in evidence, notwithstanding that the clinic affords the supreme test as regards the difficulties of coeducation, the inference seems justifiable that the schools for women offer better advantages than can be obtained in the coeducational schools.

As the great medical schools of Philadelphia, New York, and Boston do not admit women, the only basis of comparison with these schools is that afforded by the statistics of results of competitive and other test examinations to which reference has been made and which bear especially upon these particular schools, as they are in the localities where such examinations are most in vogue; and these statistics undoubtedly warrant the conclusion that the best of the women's schools compare favorably with these leading schools for men. The medical department of the Johns Hopkins University (to which the admission of women was secured by a *tour de force* in the guise of a third of a million of dollars supplied mainly by one woman) is of too recent date to throw much light on the question under discussion. This college opposes more rigid requirements to the entrance of students, and offers a more advanced schedule of study than any other medical school in this country, and yet, of the first class (which matriculated in 1893) one-sixth were women—a far higher proportion than is shown in the total number of medical students for the whole country—thus confirming my contention that the attendance of women at any particular school is not determined by the presence or absence of the coeducational feature.

The claim here distinctly put forward, that the medical colleges for women stand among the most advanced of American medical schools, is not based entirely on the two points thus far mentioned, viz., the numbers in attendance as compared with the coeducational schools and the statistics of competitive and other test-examinations, but also on their requirements for admission, the character of their laboratory and other equipments, the courses of study pursued, the clinical advantages afforded, the term of study required, and the hospital and other appointments secured by their alumnæ. On the question of curriculum, I may state that the Woman's Medical College of Pennsylvania and the Medical Department of the Johns Hopkins University are the only colleges in the United States, so far as known, in which work in the physiologic laboratory is required of every student, the former having been the first in this country to make this requirement.

The chief disadvantages from which medical women

in this country now suffer arise from their exclusion (during their professional career) from the work of the great public hospitals. Dr. Emily Blackwell, of New York, in an unpublished paper which has come into my hands, calls attention to the fact that these public institutions, equipped and endowed at public expense, are monopolized by men—although the hospital is no less important than the college in the training of doctors—that medical progress depends on the hospital and the laboratory, that the scientific writers and teachers, the great operators and other leaders in medicine are the hospital-men, and that the great journals are founded on hospital-records; and she adds that women, being limited to the few small hospitals that they have themselves established, are in the position of emigrants in a new territory, or, as might have been said, of the advance-guard of an invading army, compelled to build their own roads and create their own facilities as they advance.

This arraignment of the authorities who control the public hospitals is a most serious one; but in estimating the significance of the marked preponderance of distinguished men in the profession, as compared with distinguished women, the immensity of the mass of medical men, as compared with that of medical women, should not be overlooked. When the total number of great operators and other leaders in medicine is contrasted with the whole number of men in the profession, the ratio of greatness seems less distinguishing, "the gray pre-eminence of man" (which gave pause to the ambitious princess of Tennyson's imagination) becomes less overwhelming to the female medical consciousness. In spite of the disadvantages pointed out by Dr. Blackwell, the female profession boasts distinguished teachers in both the scientific and the practical branches of medicine, of which Dr. Blackwell herself is an example; brilliant operators in the surgical diseases of women, a field that presents some of the most difficult situations in surgery; skilful attendants in the maternal crisis that perhaps offers the supreme test of fertility of resource and presence of mind in the face of danger; and a shining record in the care of the insane, a specialty that demands a high degree of intrepidity and coolness, as well as of gentle and sympathetic firmness. The number of contributions by women to medical and scientific literature (judged by the ratio of writers to the whole number of the profession) is also creditable.[1] Without exaggeration, then, the medical profession may be said to show a goodly proportion of women who have "added the incident of learning to the accident of brains."

The medical work actually done by women may be regarded from two points of view: its value to the community (this depending on its quality as well as on its peculiar acceptability on account of their sex) and its value to themselves as a means of individual development, the latter being the broader, the more important view, a view in which the word "medicine" is quite overshadowed by the word "woman." Into the consideration of this aspect of the subject the scientific character of their work does not necessarily enter; nevertheless, the question as to what proportion of medical women may be classified as "regular," "homeopathic," "eclectic," etc., is one of great sociologic interest, like that of how the majority of women would vote in case of obtaining the suffrage, whether intelligently and on the side of law and order, or in the spirit of partisanship and with an eye (or both eyes) to the spoils.

In the city of Philadelphia (for many years, if not still, the *civitas Hippocratica* of America), of those engaged in the practice of systems not recognized by the mass of the profession as scientific medicine, systems the methods of which justify the opprobrious designation of quackery (which may be said to consist in using a remedy for the wrong reason or for no reason), the proportion is approximately the same for women as for men—about one-fifth. The statistics for the whole profession are not at hand, but of the entire number of legally qualified women engaged in the practice of medicine in the United States, made up of graduates of more than forty colleges, nearly one-fourth are graduates of the Woman's Medical College of Pennsylvania, and although I am compelled, most regretfully, to admit that this is not an absolute guaranty of the scientific character of their practice, I believe that the proportion of the alumnæ of our College who have proved true to its principles and teachings, and have thus been added to the ranks of scientific medicine, is much higher than the ratio for the city of Philadelphia.

The tide of modern medicine has set strongly in the direction of scientific methods, in which the balance and the retort, the microscope and the stethoscope, with the long list of their congeners, the thermometer, the pelvimeter and numerous other instruments of precision, the culture-tube with the measures for the exclusion and destruction of the ubiquitous microbe that have grown out of its use, and many other other sanitary measures—the results of modern study of the soil, the water, the air, and the climate—all play a conspicuous part. To this enumeration must be added the study of the lower animals and of man, by means of the multitude of modern instruments for investigation of the physiologic and psychologic problems that underlie the vast field of pathology. Any system of medicine in which the treatment of disease is based on principles and theories derived from other than scientific sources is self-condemned. So far as the medical profession is concerned, the *post hoc, ergo propter hoc* method of reasoning has had its day, and some better evidence than the recovery of the patient must be forthcoming in favor of a particular plan of treatment in order that it shall secure the serious attention of the profession; unless the relation of cause and effect between treatment and recovery can be established, we have not science, but empiricism.

In the relation which has so long existed between us of professor and student I have striven to infect your minds with the love of scientific truth; but now, as this relation is about to be severed, I desire to express to you my profound conviction of the great truth that "learning is but an adjunct to ourself;" that while she who heals the sick, who makes the blind to see, and the lame to walk does well, and "though twice a woman shall be called a leech," she who exhibits in her own character the value of a broadening and elevating pursuit in the development of the liberality of mind and self-poise essential to a true appreciation of life in all its depth and fulness does better; and while students of soci-

[1] See appendix to article by Dr. M. Putnam-Jacobi, loc. cit.

ology are still perplexedly discussing the question of the desirability of an independent career for woman in the abstract, may you, individual women, each of far higher importance than any abstraction, fare bravely and womanly on to a future in which you shall have wrested from fate—the fate of the abstract woman—an assured position among the thousands of women already living enriched and ennobled lives as doctors of medicine, who are finding therein congenial occupation, intellectual growth, pecuniary independence, and a sphere of immense usefulness to their sex and hence to the entire circle of humanity that comes within the radius of their influence.

CLINICAL MEMORANDA.

THREE CASES OF RECTAL NEURALGIA, ONE WITH DOUBLE MAMMILLITIS.

By W. F. ARNOLD, M.D.,
PASSED ASSISTANT SURGEON, UNITED STATES NAVY.

CASE I was met in the person of a rather delicate man of middle age, whose illnesses have mostly been ascribable to the common infectious diseases of the respiratory system that have been resisted with anxious difficulty, although no noteworthy sequelæ remained from any of them. He suffered severely some years ago from Morton's (pressure) neuralgia in both feet; this subsided upon the adoption of a less exacting life, without treatment, its nature appearing to have escaped observation. He is the subject of pruritus ani of so moderate a character that applications of such simple remedies as citrine ointment and an ointment of calomel twice a week have served to obviate nearly all of its inconveniences. On account of this response to agents to which I am very loath to ascribe any other than a local (and most probably a parasitic) action, I think the neurotic origin of this irritation is open to serious question. At the time of the single attack of rectal neuralgia that I witnessed, the pruritus had been in unusual abeyance; and it continued so for several months thereafter. He had gained much in weight about this time, and he frequently congratulated himself upon the beneficial effects of a recent change of climate.

This attack came on without premonition during sleep, between one and two o'clock at night; and in this manner and time of inception it exactly corresponds with the other two cases to be described, as well as in the relief afforded by the passage either of feces or of flatus even in the smallest of quantities. I found the man upon the seat of the water-closet in a state of depression, nearly pulseless, of a death-like pallor, and sweating profusely. He evinced so much pain at that time that I gave him a medium dose of morphin subcutaneously, notwithstanding his statement that it had grown distinctly less in the few minutes that had been required to summon me by the officer of the deck, who had first assisted him in a half-fainting state to the water-closet.

No further attacks were observed in the course of our service together, which continued for a year; but no antineuralgic treatment was instituted. The man thought that the attacks were becoming less frequent.

CASE II occurred in a man about forty-five years old, of pronounced athletic tendencies. There is nothing more significant in his medical history than an obstinate attack of sciatica about five years ago. His seizures have not exceeded four in all, the first having taken place nearly two years ago. They seem, from the patient's account of them, to have been milder than the one to be detailed, but he is emphatic in declaring the pain to have been agonizing in character. All occurred between midnight and two o'clock A.M. The last one or two the man relieved by an extemporized suppository, as he had noticed that the presence of anything in the lower bowel abated the pain.

In Case III the patient had suffered only two very light paroxysms of rectal pain. It is probable that they would not have been considered as characterizing a special form of neuralgia had attention not been aroused by the preceding cases. The victim is a medical man, about thirty-two years old. His history includes gastric neuralgia(?) at the age of ten, severe *tic* from exposure to cold in Glacier Bay, Alaska, and a confirmed predisposition to Morton's neuralgia in the left foot, which is kept within limits, permitting comfortable bodily activity by attending to the shape of the soles of his shoes. His health is good, although he consciously prejudices it by his persistence in sedentary employments, to the almost complete exclusion of regular exercise. There is nothing to be noted about his seizures, which he described to me minutely upon my suggesting their nature, that has not already been referred to. We agreed in declining to treat such an irregular, and, in this case, so mild a disorder.

This gentleman has been subject since early boyhood to a peculiar form of irritation of the nipples and their areolæ, which, as nearly as he can recall, is set up only by exposure to a strong, cool wind. He is reasonably certain that it is not a result of the direct, local action of a high degree of cold, inasmuch as it is not manifested at times of severe exposure to simple cold; while the protection afforded these structures by the prevailing types of apparel is certainly opposed to this assumption. Besides, he has been driven by the inconveniences experienced to adopt local protective measures that have proved to his mind to have been of no prophylactic value. The last instance of it, which he observed with minuteness, was due to four hours' exposure to a strong, topsail breeze from the northward early in April. His upper garments on this occasion—a literal wild-goose chase—were a leather shooting-coat, lined with corduroy, an otter-skin vest of southern Chinese pattern (*id est*, nearly completely double-breasted), a light flannel shirt, and a very heavy flannel undershirt.

After twenty minutes' exposure to this wind from the right rear, soreness of both nipples appeared. The sensation is described as one of rawness, which causes the patient to shrink continually from the contact of his clothing, upon which contact, however, he is confident it is in no measure dependent. He says that it is more severe than simple contact of cloth with denuded cutis would be under ordinary circumstances; and he claims for it a peculiar quality that is as invariable as it is elusive of description. No very evident tumefaction results, but a deepened color seems a constant accompaniment. Careful search has not shown that the epithelium is eroded or that any exudation of any kind takes place. Hyperesthesia to touch and to the application of universal emollient agents, such as carbolized

vaselin and glycerol, remains for from one to three days after each attack. The severity of the attack appears to be directly in proportion to the violence of, and the length of exposure to, the wind, and the duration is proportioned by the severity. Protection from the wind will arrest an attack at an early period after the inception of the initial symptoms. Naturally, inflammation here is only surmised.

Diligent inquiry has not developed a single case of this kind in either sex, save the one just related. It is perhaps desirable that I should add that there is not a suggestion of effeminacy about the subject of this, to me, unusual manifestation, which is a very real source of annoyance to its involuntary victim, who has the additional misfortune of being compelled to go to sea for a livelihood. He considers that he suffers more from cold than do the majority of the inhabitants of temperate climates. He has no theory of its mode of origin, and I have no speculations as to this that I care to express.

Regarding the rectal neuralgia, I have heard very little, and have seen even less in the commoner textbooks on the practice of medicine, although Gowers devotes a pointed paragraph to it in his *Diseases of the Nervous System*. If what I observed in Case I were frequently repeated, it might easily serve as the cause of sudden death from shock or from syncope. It may be well to state that none of these patients shows any obvious signs of gout.

SPONTANEOUS EXTRUSION OF A PIECE OF IRON THROUGH THE CORNEA.[1]

By HOWARD F. HANSELL, M.D.,
of Philadelphia;
Clinical Professor of Ophthalmology, Jefferson Medical College; Adjunct Professor of Diseases of the Eye, Philadelphia Polyclinic.

This case presents unique and distinctive interest on account of its exceptional rarity—such a termination of a similar accident, which is recognized as a serious one, is unknown to me in my experience or in literature; and, because of its suggestion of a possible prognosis in cases of wounds of the eyeball, and of foreign bodies and their retention in its interior, that has probably heretofore not been considered. When a foreign body, such as a fragment of metal, enters the eyeball, inflammation is excited by the direct violence of the traumatism, and later by the presence of the foreign body in the highly organized tunics; and, secondly, by the introduction of germs and by the chemic changes that the substance undergoes through oxidation by the intra-ocular fluids.

As soon as practicable after the injury the magnet and other means of extraction should be employed, in order to prevent destruction and atrophy of the globe and to save the patient from the disastrous effects of sympathetic inflammation. The traumatic inflammation may cause the formation of a capsule around the foreign body, in which it may lie innocuous for many years. This fortunate outcome, however, cannot be seriously considered, and, while it exceptionally solves the problem, it does not alter the safe rule that a foreign substance in the eye should be extracted with the least possible delay and injury to the sight and to the globe.

[1] Read before the Philadelphia County Medical Society, May 15, 1895.

A. W., aged thirty years, presented himself at the outpatient eye department of the Jefferson Hospital in March, 1895, complaining of pain due to the presence of a piece of iron in the left eye. I found projecting from the most inferior part of the cornea, just above the scleral margin, a dull, black, pointed object. Palpation with a spud showed that it was metallic, as a sharp click could be easily heard and a grating sensation was felt as the point of the instrument passed over it. The pericorneal vessels were markedly injected; the cornea in the immediate neighborhood was opaque; the anterior chamber was of normal depth; the pupil was mobile and cone-shaped, the point of the cone below; the iris was attached in one or two places to the anterior capsule and to the cornea at the site of the black point; the capsule was slightly opaque, with a few streaks of opacity running backward through the lens. The patient stated that fifteen years before, while breaking rocks with a pick-axe, a minute fragment of the point of the axe flew into the left eye. Severe inflammation and partial loss of vision followed. The signs of inflammation disappeared in the course of a few weeks, to recur with greater or less severity every few months. The man assured me that this was the only traumatism that had ever happened to that eye, and that he, his medical advisers, and his friends had known that the eye contained a foreign body from the time of the accident. He had hitherto declined all suggestions to have it removed. V = 20/50. Accommodation and the visual field were apparently undisturbed, though these points could not be accurately determined. The man was admitted into the hospital, and, after some fruitless attempts at removal, the foreign body was extracted by dissecting it out from the cornea. A four-volt battery, strong enough to extract the iron and to distort the cornea, was of no service in dislodging the body because its rough surfaces and edges were firmly held by corneal and inflammatory tissue. The patient recovered in a day or two, with vision unchanged. The piece of iron I have the pleasure of showing you weighs a little less than two grains.

ACQUIRED PHIMOSIS, DUE TO UNSUSPECTED VENEREAL WARTS, SIMULATING GUMMA OF THE PENIS.

By A. BRADLEY GAITHER, A.M., M.D.,
of Baltimore, Md.;
Assistant in Genito-urinary Surgery, Johns Hopkins Hospital Dispensary.

When a case of acquired phimosis is met with, it is often impossible to tell from the clinical history just what condition will be found after circumcision has been performed. Some cases, due to hard chancre, with an induration involving the whole prepuce, and having a thick discharge from the preputial cavity, show no marked points of ulceration after operation. Again, cases with moderate preputial discharge and swelling may show extensive ulceration and excavation on splitting back the prepuce.

Acquired phimosis, due to venereal warts, is rare, and almost invariably the patient will have noticed the growths, with their gradual increase in size and number, thus giving an immediate clue to the cause of the trouble. The following case may be of interest on account of the negative history as to venereal warts, and

the clinical presence of gumma, or epithelioma, of the penis.

John D., aged thirty years, an unmarried Irishman, presented himself at the Genito-urinary Department of the Johns Hopkins Hospital Dispensary on May 6, 1895, with the following history: He denied ever having had venereal disease and had never observed a sore or growth on his penis. From childhood the prepuce had been tight, but it could always be retracted without difficulty. The man had had sexual intercourse for the last time on December 21, 1894. On January 6, 1895, he first noticed a discharge from the preputial cavity. At this time the prepuce was slightly swollen and painful, so that he did not retract it. In March he went to a hospital and was given medicine to take internally, and later an injection with which to wash out the preputial cavity. After two months' treatment, during which time his condition became progressively worse, he came to the Johns Hopkins Hospital. One year before he had had sores on the scalp and some small pimples over the body, with slight alopecia. There had been no sore-throat, headache, or pain in the limbs. The glands in both groins were indolently enlarged.

On examination, a condition of acquired phimosis was found to be present. The penis, from one cm. behind the corona to the meatus, was swollen to three times its normal size; the prepuce could not be retracted at all, and was very tense. There was a free discharge from the preputial orifice. On the dorsum of the prepuce in the median line, just over the corona, there was an excavated ulcer of the size of a small bean, with a free purulent discharge and a bad odor. The cutaneous portion of the prepuce was bright-red in color, with a sharp line of demarcation one cm. behind the corona, from which point the appearance was normal. The sensation to the touch was that of a hard, uneven mass, as if the glans penis and prepuce were adherent; yet in places there was the elastic pulpy feeling of a gumma. The edema and tension of the prepuce prevented a satisfactory examination. On irrigating the preputial cavity the fluid came slowly through the opening on the dorsum of the penis, apparently taking a roundabout course.

From the clinical appearance I was in doubt as to whether the case was one of gumma or epithelioma of the penis. On the following day, under ether-anesthesia, the prepuce was slit back in the median line, through the sinus, and the condition found to be due to venereal warts. These were countless in number, and grew from every portion of the glans penis and mucous surface of the prepuce. They varied in size from a pin-head to a cherry. Under the favorable conditions present their growth had been so luxuriant as to put the prepuce under such tension that necrosis had set in. The warts were cut off as close as possible and cauterized with nitric acid. The prepuce was then rounded off and an iodoform-dressing applied. On the subsidence of the edema it was found that a few warts had been missed. These were treated with the continued local application of fluid extract of euphorbia pilulifera, which gives very satisfactory results in this condition.

2012 ST. PAUL ST.

Dr. Benjamin S. Mackie, U.S.N., died at Philadelphia on July 25th, at the age of fifty years.

TOXICOLOGIC NOTE.

A CASE OF OPIUM-POISONING TREATED WITH POTASSIUM PERMANGANATE.

SERVICE OF GEORGE BYRD HARRISON, M.D., EMERGENCY HOSPITAL, WASHINGTON, D. C.

[Reported by JAMES R. CHURCH, A.M., M.D., of Washington, D. C.]

THE following case was the last of a series of fourteen which came under my observation while an interne at the Emergency Hospital, and, I think, presents features to make it of interest to the profession. It is the only case in which a recovery was entirely attributable to the permanganate-treatment, and was to me a most satisfactory test of the efficacy of this antidote.

M. S., a mulatto girl, nineteen years of age, was brought into the hospital at 11.30 P. M., with the history of having taken twenty-cents' worth of laudanum (probably 25 or 30 c.cm.) about two hours previously. She had several epileptiform seizures while in the ambulance and one after admission to the hospital, but was easily roused from her stupor by pressure on the supraorbital nerves. She could not, or would not, talk, but was not in a condition of absolute coma. The pupils were pin-head in size, respiration was slightly accelerated, and the temperature was normal.

The girl was treated with the usual line of opium-antidotes and antagonists, and, as coma was absent, she was given apomorphin hydrochlorate 0.005 hypodermically, which had been preceded by 300 c.cm. of a solution of potassium permanganate (0.30 to 500 c.cm. of water). Two more injections of the apomorphin were given at intervals of about seven minutes, but none of them was effective. To be certain that the lack of action was not due to the defective qualities of the drug the second and third doses were each taken from a freshly opened bottle of tablets. Shortly after the last dose the girl's condition became rapidly worse. She lapsed into coma and the pulse went up to 134 and the respiration to 26, and became stertorous. The faradic current now had little effect, and I decided to rely entirely on the permanganate, as other treatment was unsatisfactory.

The stomach-tube was passed, and, after the removal of the gastric contents and lavage with hot coffee, 500 c.cm. of the permanganate-solution were thrown into the stomach and allowed to remain about five minutes, being then withdrawn and replaced by a fresh solution. This was repeated until 2500 c.cm. of the solution had been used, when 250 c.cm., containing 0.30 of the salt, were introduced and allowed to remain. After the second washing out the girl's condition began to improve, and after the last she was aroused by the battery with comparative ease. Her pulse dropped to 104 and respiration became less frequent and fuller, and within three-quarters of an hour from the ingestion of the last 250 c.cm. of solution she was sent to the ward to bed, being then perfectly conscious and easily roused. She made an uninterrupted recovery and was discharged the next day, complaining only of slight pharyngeal irritation and general lameness, the latter due to efforts to rouse her.

The points of interest in the case are, I think, the

convulsions, which I do not understand; the bad effect of the apomorphin, which had about the influence of an equivalent of morphin, and, lastly, the entirely prompt and satisfactory rally after the permanganate was resorted to, at a time when the condition was extremely critical.

I think my treatment open to criticism in deferring the use of the stomach-pump and in not immediately using the permanganate in larger dose than the first 300 c.cm. I can unhesitatingly assert that the patient's recovery was due to the permanganate-treatment, and should not hesitate to use it in other cases in preference to other drugs.

1706 Oregon Avenue.

MEDICAL PROGRESS.

Cerebral Softening with Hysterical Symptoms during Pregnancy.—Barbour (*Edinburgh Medical Journal*, June, 1895, p. 1092) has reported the case of a primipara, twenty years old, who in the fifth month of pregnancy became melancholic, and suddenly in the seventh month staggered, lost vision, and also power in the left leg, recovering, however, in a few minutes. Two weeks later a similar attack occurred, beginning with emotional disturbance, tremors, and faintness, leaving loss of power in the left arm and aphonia. On the following day six of these fits occurred, but always between them there was recovery of speech and of muscular power. The woman presented aphasia and partial aphonia, with some loss of power in the left hand. The knee-jerks were much increased, especially the left, as were also the plantar and abdominal reflexes. A month later another attack occurred, and was attended with involuntary evacuations of urine and feces, and with difficulty in swallowing from paralysis of the soft palate. There were also ptosis of the right eyelid, contracture of the right biceps, firm flexure at the right elbow, and beginning rigidity of both lower limbs. Later partial analgesia and anesthesia of both lower limbs appeared, the degree and area varying constantly. There were also marked fugitive flushings, sweating, and pallor, but no wasting. The temperature and pulse were normal. The case was treated as one of hysteria, which it was thought might be relieved by inducing labor, but uterine contractions came on spontaneously. Each pain was attended with minor epileptiform spasms, and the fetus died during the progress of labor, forceps being required for its extraction. For thirty-six hours afterward it appeared as if the woman would recover, but pulse and temperature rose, the reflexes became abolished, and the heart failed.

Upon post-mortem examination an area of softening was found on the right side of the brain, involving part of the head of the caudate nucleus and the anterior limb of the internal capsule. Many branches of the right middle cerebral artery were found to be thrombosed. An area of softening was also found in the middle of the pons, where the basilar artery was thrombosed. The kidneys contained commencing cortical miliary abscesses. The fetus presented contractions of all the limbs almost identical with those exhibited by the mother.

Coma from the Application of Carbolic-acid Compresses to the Skin.—Lucas and Lane (*Lancet*, No. 3744, p. 1362) have reported two cases in which symptoms of intoxication resulted from the application to the skin of compresses saturated with a solution of carbolic acid. The first occurred in a boy of fifteen years, who presented several sinuses upon the right thigh as a sequel of suppuration in the course of an attack of typhoid fever. At noon a carbolic compress was applied over the seat of operation. In the evening the lad appeared sick, and at 2.30 A. M. on the following morning he was found insensible and breathing stertorously. The pulse could not be counted at the wrist, but the heart-beat was 200 per minute. The pupils were moderately small, but reacted slightly to light. The corneal reflex was absent. There was general muscular resolution, but sharp stimuli excited slight movements. Perspiration was profuse. After energetic treatment with brandy, strychnin, and hot-water bottles consciousness returned in the course of eight hours. The urine first passed was dark in color. For several days the patient felt sick and vomited from time to time. A week after the accident, when arrangements were again made to operate, a 5 per cent. solution of carbolic acid was applied on lint to the affected part for a short time. Soon the boy was noticed to be sick and suffering and the skin was bathed in perspiration. The temperature fell below normal and the pulse became scarcely perceptible. For two days afterward the urine was dark in color.

The second case occurred in a boy, six-and-a-half years old, who presented a swelling in the right iliac fossa, which it was proposed to explore. To the skin, over and in the vicinity of the mass, there was applied at 12.20 a compress moistened with carbolic lotion, one to twenty. At 1.30 the child was heard groaning and was found to be pale, collapsed, and comatose, with marked dyspnea, convulsive twitching of the eyelids and limbs. The condition improved upon injection of ether and atropin hypodermically, and brandy by the rectum and the application of blankets and hot-water bottles. The patient thereafter rapidly improved and was quite well after the lapse of several days. In this case repeated vomiting also occurred, and the urine presented a dark-green color, yielding the ordinary reactions for carbolic acid and its products in the urine.

The Bacteriology of Acute Articular Rheumatism.—Singer (*Wiener klinische Wochenschrift*, 1895, No. 25, p. 449) has studied the urine in seventeen cases of acute articular rheumatism, with the result of finding the staphylococcus pyogenes albus in ten (and twice in the blood); the staphylococcus pyogenes aureus in one; the streptococcus pyogenes in three; and the staphylococcus pyogenes albus and the streptococcus pyogenes together in two. In one case, complicated with cystitis, an abundance of bacteria coli were found. Seven of these cases occurred in men; ten in women. Nine were severe; two moderately severe; and six mild. None presented cardiac complications.

Chvostek (*Wiener klinische Wochenschrift*, 1895, No. 26, p. 469) has examined the urine in twelve cases of articular rheumatism, with negative results in nine; in the remainder the diplococcus ureæ was found in one, the staphylococcus pyogenes albus in the second, and large

plump cocci in the third. The urine in these cases was obtained with a catheter, and it is pointed out that staphylococci and streptococci have been found in the urethræ of healthy individuals. It was further insisted upon that the mere presence of micro-organisms in the urine is not necessarily indicative of any relation on their part to disease. Further examination of the blood and urine and the contents of the inflamed joints in various conditions yielded negative results in cases of rheumatism, although organisms were found in cases of sepsis and gonorrhea complicated by joint-involvement. The opinion is finally expressed that the articular lesions of acute rheumatism are not attributable to direct bacterial invasion, but to the action of toxic substances present in the blood, due directly or indirectly to the activity of bacteria.

Skin-grafting from the Lower Animals.—At a recent meeting of the Edinburgh Medico-Chirurgical Society, Mr. MILES (*British Medical Journal*, No. 1795, p. 1149) presented a communication upon skin-grafting from the lower animals. The animals used were dogs, rabbits, kittens, and frogs. Dogs were preferred, and frogs were found the least satisfactory. In all instances but one, young animals were employed. The surface of the ulcer to be treated must be aseptic, and the patient in good health. In the majority of cases granulations were planted on. The animal was killed, or pithed, stretched out, and nailed down. The flanks and abdomen were shaved and washed with an antiseptic solution. Small pieces were cut out, the largest being six inches by one inch, but mostly much smaller. The subcutaneous tissue was always taken with the skin. The grafts were pressed on the tissue close to one another, then dressed with ordinary protective and iodoform-gauze. The first dressing should be seventy-two hours afterward, and this should be done very gently; after that, every twenty-four hours, or at most forty-eight hours. Among the difficulties encountered was sloughing of a graft, usually due to too early dressing, though sometimes to hemorrhage under the graft. Apparent sloughing of the graft was sometimes seen, though, after all, the skin grew quite well. The formation of pustules was sometimes observed; sometimes granulations grew through the graft and destroyed it. Copper sulphate had been tried to prevent this, but without success, and a sharp spoon was used instead. Ulcers upon the abdomen and thorax responded less satisfactorily than ulcers situated elsewhere, on account of movement. For this reason a loose dressing is indicated.

Treatment of Prostatic Hypertrophy by Ligature and Division of the Vas Deferens.—ISNARDI (*Centralblatt für Chirurgie*, 1895, No. 28, p. 657) has reported the case of a man, seventy-two years old, who for a year had suffered with symptoms of prostatic hypertrophy, which had failed to yield to the usual therapeutic measures. Relief was afforded by ligature and division of the vas deferens. Six-and-a-half weeks after the operation retention of urine and incontinence had disappeared, and the bladder was tolerant of urine for seven hours during the night. The urine, which had previously been purulent and at times hemorrhagic, had become clear and otherwise normal. The prostate itself, which, prior to the operation was of the size of a half-nut, became scarcely appreciable upon rectal examination. The vas deferens from the point of division pursued an irregular course and was thickened and nodular in places. The epididymis was smaller than normal, particularly at its distal extremity and in its body. The testicle itself was reduced about one-half in size.

The Toxicity of the Urine in Variola.—AUCHÉ and JONCHÈRES (*Revue de Médecine*, 1895, No. 6, p. 480), as a result of the study of the urine in a series of cases of variola, found that in the discrete variety the absolute quantity of urine is variable in different cases, while the urinary curve is more nearly comparable, being relatively high in the eruptive stage, declining in the suppurative period, and again rising during defervescence. In several cases an apparent critical secretion of urine was observed. The toxicity of the urine remained about normal during the eruptive stage. It declined, and sometimes in notable degree, during the period of suppuration, the fever increasing notably with the onset of defervescence, and again becoming normal at the end of from one to three days. Often there was at this time a veritable urotoxic discharge corresponding with the urinary crisis. In cases complicated by febrile disorders during convalescence the toxicity declined, but increased with the subsequent fall of temperature. The delirium of the acute period of the disease is believed to be of toxic origin, and in one case the oscillations in the urinary toxicity were found to correspond with the mental manifestations. In hemorrhagic variola the urinary curve and toxicity were low, almost up to the occurrence of death.

The Relation of Endometritis to the Reproductive Process.—At the meeting of the German Gynecological Society, recently held at Vienna, DÖDERLEIN (*Centralblatt für Gynäkologie*, 1895, No. 26, p. 701) attributed pathologic importance to the presence in the uterine cavity of the puerpera of micro-organisms of any kind. The designations catarrhal, purulent, diphtheric, and gangrenous puerperal endometritis may well be replaced by the etiologic qualifications pyogenic and sapremic. Pyogenic endometritis is the most frequent affection of puerperal women. The profound constitutional infections occurring during the lying-in are, as a rule, attributable to this condition. The cause is most often the streptococcus pyogenes, but it may be due besides to the staphylococcus, the gonococcus, and the bacterium coli. The micro-organisms of sapremic endometritis are as yet unknown.

Influence of Ether and Chloroform upon the Kidneys.—As the result of an extended study conducted in the surgical department of the new General Hospital at Hamburg, EISENDRATH, of Chicago (*Deutsche Zeitschrift für Chirurgie*, B. xl, H. 5 and 6, p. 466), arrives at the conclusion that previously existing albuminuria is more frequently increased by ether than by chloroform; and that albuminuria is more frequent after chloroform-anesthesia than after ether-anesthesia, and in the proportion of 32 to 25. The influence of both anesthetics upon the amyloid kidney is alike. Cylindruria, with and without albuminuria, is equally frequent with chloroform-anesthesia and ether-anesthesia, but disappears more rapidly after the latter than after the former.

SATURDAY, AUGUST 3, 1895.

CONCERNING "DYSPEPSIA."

From the amount of pepsin on the market we would certainly be led to believe that so-called dyspepsia is a well-defined disease. There is a sort of poetic justice about the fact that the American hog, whose lard and pork are commonly held guilty of what is often spoken of as our national malady, should now furnish the popular remedy therefor. We might almost transpose "a hair of the dog that bit you" into "a stomach of the pig that upset you," for according to the popular view at least, "dyspepsia" is looked upon as a disease of the stomach. The public knows perfectly what "dyspepsy" is and just what to take for it. Pepsin, in some form, is poured into our feeding-bottles at the dawn of our existence; it is kept upon our pantry-shelves like sugar or soda; it surges and bubbles in our soda-water; it lurks in our chewing-gum. We smuggle peptones into the economy with the bouillon that opens the banquet and in the jellies that crown its close. It looks as if the stomach would soon become a supernumerary organ, like the third molar—and the mammary gland of modern woman. Whence has arisen this deep-rooted idea? From the medical profession, of course. In fact, medical men are almost as fatuous as the community in regard to pepsin, prescribing it in every emergency as they used to prescribe calomel fifty years ago. And yet the dyspeptic is abroad in the land as never before.

We are all proud, and justly so, of the rapid strides that have been made in the pathology of disease in the last thirty years. Probably no one principle has done more to clear our diagnosis, systematize our pathology, and advance our therapeutics than that of rigidly sifting and resifting the evidence until the one organ has been found that is chiefly responsible for any given disturbance. But have we not carried the process too far in some cases? We do not refer simply to such wild-goose applications of it, as, for instance, graduated tenotomy for epilepsy, cauterization of the turbinates for asthma, or repair of the cervix for neurasthenia, but to more rational and generally accepted results of the method. For instance, it was a great advance and triumph when Bright discovered that the complexus of symptoms that bears his name was caused by disturbances of the filtration-processes in the kidneys. But does any thoughtful physician to-day regard so called Bright's disease as primarily and essentially a disease of the kidneys? Are these organs not simply vicarious sufferers for the shortcomings of either the liver-cells or the muscle-cells, resulting in a poisoning of the arterioles in the body generally? The glomeruli simply suffer as part of the vascular system. Are we not also beginning to suspect something of the same sort in regard to pulmonary tuberculosis? We know all about tubercle anatomically, and the bacillus has become one of our household gods, a word to conjure with, an explanation for everything; but why is it that this organism has in nine cases out of ten to attack the lungs before it can pull down his prey? It effects an entrance into every part of the system, but in the lungs alone can it usually produce a fatal result. It would appear as if pulmonary tuberculosis were not so much a disease of the lungs as that the latter were a point of least resistance for the whole system.

Something of the same sort appears to be true of the disturbance of digestion called dyspepsia. We use the term "dyspepsia" simply as one of convenience, as describing not a disease, of course, but a well-known group of symptoms, usually referred to the condition of the gastric mucous membrane and contents. There can be little question that the stomach has been held responsible for far more than it deserves. In the first place, many of our

worst dyspepsias are really, to coin a term for the moment, "dystrypsias," and dependent upon enteric and pancreatic disturbances; others again are of hepatic and even cholecystic origin; while most cases of "gastralgia" are really anginal and of cardiac origin. But apart from all such confusions, is the stomach or its contents essentially and solely responsible in the large class of dyspepsias that are of "gastric" origin? Our enthusiastic bacteriologic friends say yes at once; the contents alone are to blame. Tell them what germ has been ingested with the food and they will be able to state in advance what form of indigestion will result. They are now seriously proposing a classification of gastric troubles, lactic, butyric, gaseous, and yeasty dyspepsias, according to the germs that give rise to these various fermentations. *Gastritis oidica albicans, gastritis torulosa*, sound well, but we think there are valid objections against regarding the gastric mucosa as simply a culture-plate for germs at the sweet will of the latter. On the other hand, the medical man is also inclined to blame the contents of the stomach, as his first question usually is, What have you been eating lately? and if pork, or pie, or cake is mentioned, he exclaims triumphantly, "That's what did it," and prescribes pepsin, followed by a saline; forgetting that there are hundreds of men, women, and children in the rural parts of that very community who habitually have soda-biscuits and doughnuts for breakfast, fried pork and mince-pie for dinner, or baked beans and "oak-bark" tea for supper, and never find out that they have a stomach.

We are supposed to be a nation of dyspeptics. This peculiarity is variously attributed to the use of the frying-pan, mince-pie, too rich foods, hurried meals, tobacco, and insufficient mastication. Abernethy held these views as to mastication, for his crusty advice to the rich American who consulted him for indigestion was simply to expend upon his food the jaw-power that he wasted upon his quid and the saliva that he squandered upon his carpets.

Part of our troubles are no doubt due to the thoughtless way in which we revel in the cheapest, most varied, and abundant food-supply the world has ever seen. More may be traced to our senseless neglect of the comforts and decencies of the table—and as of almost anything else—in our mad rush after the nimble dollar.

But these causes alone are by no means adequate, for we must remember that if our American dietary is prodigally rich and varied, it is also the most abundant, the most nutritious, and, broadly considered, the most easily digestible in the world. We know nothing of the insufficiency, the coarseness, the deadly monotony of European peasant and even middle-class diets; while as for indigestibility and "unhealthiness," what have we to compare with sauer-kraut, boiled dough, cabbage-soup, black bread, unleavened "leather" cakes, and raw sausage? Our "twenty-minutes-for-dinner" style of eating is no doubt injurious, but even in this connection our cookery has been adapted to our habits and everything boned, minced, hashed, and cooked to a pulp, so that our teeth are actually decaying from lack of exercise. It is the rush back to work *after* the dinner that does the mischief, and not the mere mechanical obstacle of imperfectly masticated food.

But the most fatal objection to this theory lies in the fact that the mass of our dyspeptics are "dieters" to a man—or woman. They talk "health-foods" from dawn to dark; they abstain from biscuit, from fried cakes, from the pleasant pie and the juicy cabbage; they shudder at the mention of pork, "anything that has lard in it" is as an unclean thing to them. They mortify the flesh on Graham gems and similar atrocities, on oat-meal and germ-foods, on quarts of hot water and slops of every description—and still they suffer. The more carefully the diet is "regulated" the worse, as a rule, is the "dyspepsia."

When any man attempts to substitute his own puny "reason" for the instructive wisdom of a thousand generations he usually makes a mess of it. Digestives give only temporary relief. The trouble is not with the food, nor yet with the stomach, but with the whole individual. Take one of these valetudinarians out into the open, put an oar or a fishing-rod into his hand, or a twelve-bore across his shoulder, and let him thrash the streams or tramp the uplands from dawn to sunset, and what of his dyspepsia? Within forty-eight hours he will be devouring the swimming salt pork, the substantial sausage, and the alkali biscuit of his farm-house fare with relish and impunity. His muscles loudly demand such pabulum, and their servant, the stomach, takes care of it, as ordered, without remonstrance. In short, in most cases of dyspepsia the stomach is the point of greatest stress and strain in a generally enfeebled and devitalized organism, and consequently the place where the

breakdown occurs. Let the business "hustler" and the model housekeeper relax the strain and tension and their dyspepsia will improve *pari passu*.

Discomfort here, as elsewhere, is a danger-signal that should be heeded and brakes whistled down at once, instead of being muffled by pepsin. Even regulating the diet is at best a mere palliative and a serious mistake ultimately. The pressure on the stomach is lightened thereby, but the strain on the whole system continues unchecked. More than this, "regulation" usually involves the substitution of less nutritious and substantial foods than before, and the *circulus vitiosus* is actually strengthened thereby. The stomach refuses to digest fats and proteids because its blood-supply is of poor quality; it is humored with sugars, starches, milk, etc., and thus the blood is cut off from the very supplies out of which it might have repaired its deficiencies and sinks more deeply in the mire of degeneration.

Pepsin and dieting in such cases are but little more rational than the use of opium. We ought to go to the root of the matter and never rest satisfied until our dyspeptic patient's stomach is in such condition that it will digest *anything* in reason that he puts into it. We should insist upon whatever possible changes in his hours, responsibilities, habits, and recreations may be necessary to attain this standard. A dyspepsia cured by dieting is a dyspepsia uncured. To relieve gastric distress in such cases by reducing and watering the diet is like easing a crushing machine by increasing the distance between its rollers; it continues in operation with less motive power, but what sort of work does it do? A man may continue to exist on Graham bread, milk-toast, beef-tea and gruel, but he does not really *live*, still less grow and repair waste.

Instead of encouraging our patients to avoid everything that "disagrees" with them, we should urge them to a persistent effort to make everything agree with them. Let us insist that they make themselves not merely "stomach-hungry," but "muscle-hungry" every day, and all other things shall be added. Our standards of "dyspepsia" have been altogether too low in the past. Any sort of a diet that could be devised that a man could shuffle along upon, extracting a living out of it, without actual discomfort, has been considered sufficient. An able-bodied stomach, even less than this, a really "practical" digestion, must be capable of assimilating not only all digestible things, but a great many so-called indigestible ones as well. A cruiser that is to steam ten knots an hour as a routine pace must have a possible speed of at least fifteen knots under pressure. It would not be a bad idea to fix upon a "standard food" that our dyspeptic stomachs should be required to digest before being allowed to consider themselves cured—pork, for instance, for, leaving idiosyncrasy out of the question, any one who cannot digest this in the form of breakfast bacon or ham ought to be regarded as dyspeptic *in posse*, if not *in esse*, or, to borrow a term from circulatory pathology, as suffering from "gastric inadequacy." As a matter of fact, almost every Gentile whose dietary does not include pork in some form is either dyspeptic or will soon become so. Dyspepsia is emphatically a disease of under-feeding, instead of over-feeding. In practice one will see more cases cured by pork than by pepsin.

Dyspepsia should be treated as a symptom sometimes—as we are at last learning—as a reflex neurosis, and essentially as a systemic instead of a gastric disease, and it will cease to be one of the *opprobria medicinæ*.

EDITORIAL COMMENTS.

"*Publishing the Formula*" is a delightful recreation of the *fin de siècle* nostrum-vendor. One wonders which most to admire, the enormous impertinence of the "publisher" or the gullibility of the public. Perhaps it may turn out that the egregious ascription of stupidity to the asinarian public, professional or lay, is the only thing to wonder at. For how can men think to hoodwink even the stupidest people nowadays by such a gambler's game of now-you-see-it-and-now-you-don't? *Can* people be bamboozled by such nonsense, and *can* the bunco-men be guilty of such attempts as the jingling together of a lot of chemic names and calling that a formula? Verily, men are driven to desperate straits when they do such things. The latest instance is contained in a pamphlet now before us, entitled (of course) "a new consumption-cure." The author thus delivers himself:

> I may add that there is a further reason for reluctance in setting forth the claims herein presented. It is the inevitable violation of "the sanctities" of Medical Ethics—the excitement of prejudice on the part of many physicians—incident to advocating a so-called "Secret Remedy." For this, however, I can only express a sincere regret, without in the least apologizing for my position.
>
> I am not an M.D., and so not amenable to any professional Code of Ethics. The broader ethics of civilized humanity accord to every man proprietary rights in the discoveries as well as the creations of his own genius. The just sentiment of mankind in general as well as my own conscience will sustain me in retaining that right, at least for a time, through the only possible means—keeping my formulas and modes of manufacture to myself. I am, moreover, happy in the assurance

that there are men, even in the ranks of regular medicine, broad-minded and generous-hearted enough to accord me that right without cavil. They will examine the evidence, and, upon proof, will acknowledge gladly the improvement made upon any methods known to them of combatting the worst disease with which they have to contend. Enough such men there are to afford me all the "moral support" needed in facing the opposition of their more numerous, but less noble brethren. I may be pardoned, too, for saying that the renunciation of "secret and proprietary remedies" on the part of the medical profession is, I am informed, to a very large extent a virtue held more in theory than in practice. To a still larger extent it is a rule of faith, ignored as wholly obsolete.

"Nine-tenths of the profession"—I quote from one of its own members who has ample knowledge of the facts—"nine-tenths of Medical Practitioners are daily using and prescribing drugs and compounds whose exact composition and mode of manufacture they do not know. These are practically 'secrets' belonging to the pharmaceutists, who put forth these remedies with the most voluminous and attractive forms of advertisement possible."

Thus the benevolent discoverer squares his conscience in accordance with that of the "broad-minded and generous-hearted" secret-nostrum men, and against the "more numerous, but less noble brethren" who have no therapeutic secrets. (It is an interesting psychologic study to see how the lower one sinks in the slime of selfishness and quackery and deceit, the more he prates of broad-mindedness and brotherly love, and swashes about in the slush of maudlin sentimentalism.)

But a later pamphlet shows that our new-consumptive-cure man was not quite satisfied with his broad-mindedness, etc., for here he makes a great hullabaloo in the *Rocky Mountain News* about publishing the secret. At last "THE FORMULA IS HERE," and it reads thus:

Up to this time we have not revealed the constituents of the gas, but feel that it is now time to do so, and learn whether or not, since it is open to the profession to know the truth without violation of ethics, they will take heed of it. I will take this step because a number of physicians who have witnessed the results of my work think it may be the opening of a new era to medicine. So, without attempting to detail all the steps of my discovery, I name those elements which constitute the essential active principle in the Electro-Inhalent Consumption Cure.

Formula—Calc. chloride, Potas. bromide, Potas. chlorate, sodium chlor., alum. c. p. oxygen.

These elements, treated with static electricity, give rise to an antiseptic gas of the most peculiar form. It is unlike anything else hitherto known, both in nature and effect, etc.

We would not have occupied so much space with this trash if the method of exploitation did not seem to run the danger of becoming fashionable, even in some so-called medical circles.

Intrauterine Conveyance of Typhoid Fever.—While clinical evidence has not been wanting of the transference of disease from the pregnant mother to the fetus *in utero*, the subject has been much enlightened with the progress of bacteriologic science. Although one cannot in strict construction speak of tuberculosis being inherited, a number of observations have shown that the offspring of tuberculous mothers may be born tuberculous. We have in this instance, however, much the same kind of transmission of the disease as may occur at any time from one infected person to another, albeit in the nature of things more direct—but this is not heredity. The conveyance takes place through the intermediation of the placental blood, and in the same way as the infection of the mother took place, and is not developmental. The same processes are active in the infectious diseases as a group, but the demonstration has not yet been generally made. In this connection an exceedingly interesting observation has been noted by FREUND and LEVY (*Berliner klinische Wochenschrift*, 1895, No. 25, p. 539), who have reported the case of a woman, twenty-four years old, who in the fifth month of her third pregnancy was attacked with typhoid fever. The highest temperature reached was 104°, and the variations for two weeks ranged between this and 100.4°. In the fourth week of the disease, when the temperature rarely exceeded 101.3°, the fetus was rather suddenly expelled. A single vaginal examination had been made with the greatest care, the hands being disinfected with mercuric chlorid, the external genitalia being washed with soap and water, and they and the vagina irrigated with lysol, followed by the application of a cotton pad. The fetus was directly received into a sterilized glass vessel, but lived for only a short time. There were no complications and the woman went on to recovery. The uterus contracted well, and the placenta, which was expelled within a short time, was received into the same vessel as the fetus. The placenta was distinctly marginate; the entire decidua remained in the uterus, but was readily detached with the finger. In the sixth week after delivery the woman suffered a relapse of the fever, lasting ten days. Twenty minutes after the birth of the child cultures were made from the splenic fluid, the blood, and the placenta. In the course of three days a number of typhoid-colonies were found in the placental and splenic inoculations. Similar colonies also developed upon plates prepared from bouillon into which a portion of spleen had been thrown, and which had been kept in a thermostat for twelve hours at a temperature of 98.6°. The fetal spleen was slightly enlarged and soft, but the intestines presented no lesion. Neither hemorrhage nor infarction nor other noteworthy morbid change could be detected in the placenta.

In this case the expulsion of the fetus must be attributed to the infectious process with its concomitant manifestations, for both the placenta and the fetus presented no well-defined evidences of disease.

The Bicycle-ambulance and the Bicycle.—From Germany comes the news of a novel utilization of the bicycle that seems likely to be of considerable interest and value to the medical profession. One of the ingenious city physicians of Berlin has invented an emergency-ambulance consisting, roughly speaking, of a narrow spring-cot supported upon the frames of two bicycles and a third wheel. The cot is hung upon an elaborate set of springs and is provided with a water-proof coop-like cover of canvas stretched over steel bows, which can be readily lifted on and off like a lid. A seat is arranged at the head of the bed, over the third wheel, for the doctor, beside which is a box for remedies and dressings. Thus the physician (if young and active) and one attendant can

rapidly propel the machine to the site of the accident, while the patient is placed upon the cot with the doctor seated where he can give his whole attention to the former, and the outfit is propelled back to the hospital. The ambulance is so light and strong in construction that the run can be made at quite as high a rate of speed as is compatible with safety. The advantages are obvious—no horse, feed, or stable is required (the latter with its large space-requirements and odors being quite an item in city hospital-premises). No shed is needed for the vehicle and horse to stand in while awaiting a call; there are no delays, *e. g.*, in ordering by telephone from the stables, etc. The machine can be kept in the receiving-room or entrance corridor, and with wide doorways and a gangway at the entrance-steps can be pushed with its burden right into the ward and the patient lifted directly upon his bed. We are already much indebted to the bicycle as a most beneficially athletic substitute for the traditional "doctor's cart," as a new and attractive "oxidation-prescription" for our patients, as a means of giving city-prisoners a knowledge of the country, etc. Perhaps there should not be omitted a word of praise to it as the only influence in nineteen centuries that has had the slightest appreciable effect in inducing women to make a rational modification in their attire. For this let us bow before "the wheel" with grateful respect, for it has done more in ten years than we have in as many generations—it has made an impression upon the fashion-plates. Will it bring about the abolition of the petticoat-abomination? The skirt, may we believe, is at last "divided against itself," and perhaps even the corset will be scheduled as the next to "go." One cannot "scorch" in a strait-jacket. All honor to the bicycle! It has made a breach—we will not say breeches—in a rampart against which the united forces of the profession, the bench, and the pulpit have surged in vain.

The Treatment of Typhoid Fever with the Serum of Immunized Animals.—We have on previous occasions cited experiments in the treatment of typhoid fever with the serum of convalescents[1] and with the products of bacterial activity.[2] It was to be expected that the recent developments in the antitoxic treatment of diphtheria would stimulate renewed activity in this direction, even though it is not yet possible to reach a final conclusion.

As a contribution to the progress in this field of investigation Klemperer and Levy (*Berliner klinische Wochenschrift*, 1895, No. 28, p. 601) detail the results of a series of interesting observations upon the influence of the milk and serum of immune animals in preventing typhoid fever and ameliorating an already existing attack. As, on account of the long course of the disease, repeated treatment would be necessary, it was at once seen that considerable quantities of the immunizing fluid would be required, the first experiments were undertaken with the milk of immune animals. This was readily obtained by immunizing a goat. It was found that this method was impracticable, as the immunizing influence of the milk was lost by ingestion through the stomach, and injection into the bowel, though efficient, is obviously not feasible in typhoid fever. It was, therefore, finally concluded that resort would have to be had to blood-serum. With this end in view the dog, as having considerable natural immunity to the disease, was selected as the most suitable animal. By treating dogs with gradually increasing amounts of bouillon-cultures of typhoid-bacilli it was possible not only to immunize susceptible animals, such as mice and guinea-pigs, to the action of virulent typhoid-bacilli, but also to effect a cure of the attack when treatment was instituted some time after infection had been established.

After it had been determined that the serum thus obtained was innocuous when administered to human beings in small quantities by subcutaneous injection, the treatment of five patients with typhoid fever was undertaken. Each of these received three injections on successive evenings. These were well borne and gave rise to no discomfort, or exanthem, or albuminuria. All of the cases were in the first week of the disease, and all pursued a mild course. It is admitted that the disease was not aborted by the treatment, although it was thought the attack was simplified and abbreviated, the natural immunity being hastened. At the same time the observations show that the treatment is perfectly harmless.

Chronic Inebriety and its Incurability.—In the annual report of the Walnut Lodge Hospital for Inebriates, Dr. T. D. Crothers gives a record of 66 patients that had been treated in the institution previous to 1885. Of this number 21 are dead, having relapsed and brought on death by their excesses, 16 are living orderly temperate lives and can be considered cured, 4 are insane, 10 are hopeless inebriates, and 15 are given to occasional sprees. The small percentage of permanent cures is somewhat discouraging, though, as a rule, only the more chronic drunkards seek hospital-treatment.

Of 58 inebriate patients treated in 1894, 43 had been in other institutions previously. The number of relapses from the so-called "gold-cure" is increasing, and Dr. Crothers finds symptoms of acute insanity common among such individuals.

The chronic inebriate must be handled in a different way from the acute alcoholic. Some States have a so-called Habitual Drunkard Act, under which persons arrested several times for drunkenness can be committed to an inebriate-asylum for an indefinite period of time. If all chronic drunkards were thus treated and kept under lock and key, the cost would no doubt be very great, and yet only a tithe of what it is at present. Persons have been sentenced to imprisonment thirty and more times a year for drunkenness. More than one-half of all arrests are for this cause. The chronic drunkard is a constant menace to society, a clog on the wheels of industry, and the amount of trouble that he causes is incalculable. He must be restrained, as the lunatic is, for the safety of society.

A "Pathological Meeting."—According to a notice in *The Lancet* of June 29, 1895, "A Pathological meeting of the Neurological Society will be held on July 11th." And notwithstanding many such things, our humor-loving and kind-hearted British friends find much pleasure, to which, of course, they are heartily welcome, in measureless contempt and scorn of "Americanisms."

SELECTION.

VIVISECTION AND KINDNESS TO ANIMALS.

ACCORDING to the biographic sketch of Professor Mosso, Ludwig, the greatest of vivisectors, was President of the Leipsic Society for the Protection of Animals, and remained to the last one of its most active members. Germany owes it to him that her horses and beasts of burden are now humanely treated. To him is due that awakening of the true humanitarian spirit toward the brute creation that culminated in the "Verband der Thierschutz-Vereine des Deutschen Reichs" (Union of German Societies for the Protection of Animals). It was mainly from her sense of the gentler attitude to be encouraged toward animals on the part of the rising generation that Leipsic made him an honorary citizen on the fiftieth anniversary of his graduation in medicine. "No physiologist," continues Professor Mosso, "has ever sought with greater frankness than he to impose just limits on vivisection. The gates of his institute were ever open to all who wished to assure themselves that he, in the midst of his experiments, knew how to spare suffering. The vivisector's art attained such perfection in his hands that, having to sacrifice an animal, he did not let it feel that it was even being tied. He would apply the muzzle and instantly proceed to the exhibition of ether or chloroform, which, in a few seconds, in a dog, for example, made it insensible." "It is an error," adds Professor Mosso wisely, "to believe that experiments can be performed on an animal which feels. The perturbation induced by pain in the functions of the organism is so profound as to render useless the experimenter's study. It was Ludwig who uttered the celebrated *mot* that some physiologists, to study the nervous system, act like him who fires a pistol into a watch to see how the chronometer works. Suffering ought to be entirely eliminated from physiological experiment, because the instruments we employ to-day are so delicate that they become unserviceable the moment the animal is agitated or moves."—*Lancet*, No. 3748, p. 1651.

REVIEWS.

A TREATISE ON THE NERVOUS DISEASES OF CHILDREN, FOR PHYSICIANS AND STUDENTS. By B. SACHS, M.D., Professor of Mental and Nervous Diseases in the New York Polyclinic, etc. Pp. 666, 162 illustrations. New York: William Wood & Co., 1895.

This book, written by one of the ablest of American neurologists, is a valuable contribution to neurology and pediatrics. It contains much original material, and everywhere bears the impress of the author's experience.

In an interesting introductory chapter are given the author's methods of investigating nervous disease in children, including various examination-schemes and the modes of testing vision, motion, sensation, and the like.

The general arrangement of the book is simple but good. Part I is devoted to general nervous diseases, under which head are included convulsions, epilepsy, hysteria, chorea, tetanus, tetany, headache, disorders of sleep, vasomotor affections, and trophoneuroses. Organic diseases of the nervous system are considered in Part II, chiefly under two heads, organic diseases of the spinal cord and organic diseases of the brain, but with two prefatory chapters on diseases of the peripheral nerves. As might be expected, the author has had considerable difficulty in determining what diseases to include and what to omit, as many of the nervous diseases of children also occur in adults. He has, however, exercised good judgment in this respect, very properly not discussing tabes and some of the forms of sclerosis; on the other hand, considering such disorders as epilepsy, hysteria, and tetanus, which occur both in children and in adults, and in children have points of special importance. Huntington's chorea and progressive muscular atrophy of the Aran-Duchenne type have also been properly given a place, these affections needing to be related to and contrasted with the dystrophies, atrophies, and choreas and family forms of disease occurring in children.

The chapters on diseases of the spinal cord and of the brain are introduced by careful but not too elaborate discussions of their anatomy, physiology, and pathology, excellent judgment and discrimination being displayed in the selection of the material, which has been drawn from the work of the most recent investigators.

In a brief appendix are given a few valuable therapeutic suggestions.

A notable and valuable feature of the work consists in the tables of differential diagnosis scattered throughout the volume, and evidently prepared with great care. They will prove of particular value to students and general practitioners. An especially valuable table for practical purposes is found in the introductory chapter, under methods of investigation. Beginning with the ciliary and sphincter iridis muscles and proceeding to the quadratus lumborum and abdominal muscles, this table gives in parallel columns the names of all the important muscles with their normal functions, the symptoms of deficient action, innervation, and the diseases in which the muscles are commonly involved.

Space will not permit an analysis of the book worthy of its contents, and where there is so much to approve it is difficult to pick out special portions for commendation.

Many of the shorter articles, such as those on abscess of the brain and sinus-thrombosis, are compact yet lucid expositions of the subjects considered. The discussion of infantile cerebral palsies is the best in any text-book, showing much original work, clinical, histologic, and pathologic. Muscular atrophies are thoroughly discussed, the points of distinction between the spinal, neural, and myopathic forms being clearly brought out both in text and tables.

Under the head of hereditary or family diseases of the spinal cord are included hereditary ataxy, hereditary spinal paralysis, the family type of progressive muscular atrophy, etc. It would probably have been best to put in this same category of family diseases hereditary chorea, Thomsen's disease, and congenital paramyotonia, as, strictly speaking, these affections are not spinal or cerebral, but cerebro-spinal and of embryonal origin.

The chapter on insanity is brief but sufficient for a general work on the nervous diseases of children.

Particular attention has been given to the subject of arrested and aberrant development, and the evidences of this work are seen in several portions of the book, es-

pecially in the chapters on defective development of the brain and on idiocy and imbecility.

Short bibliographies are appended to each chapter. Although thoroughly acquainted with foreign neurologic literature, the author has not neglected the writings of his own country. The letter-press and illustrations are of the highest order.

—

First Annual Report upon the Births, Marriages, Divorces, and Deaths in the State of Maine for the Year ending December 31, 1892. Augusta: Burleigh & Flint, 1894.

This report was compiled by the Secretary of the State Board of Health, Dr. A. G. Young, in accordance with an Act of Assembly approved in 1891. The statistical tables are accompanied by "Notes" elucidating the data presented, and containing instructive comparisons and comments.

The birth-rate for 1892 was 21.21 for each 1000 of the population; and for each 100 girls born there were 106.7 boys, a preponderance of the births of boys "which conforms with the results of the registration of births almost everywhere." The marriage-rate was 8.56 to every 1000, and there was nearly one divorce to every ten marriages solemnized!

The death-rate was 18.37 to every 1000 of population as returned by the census of 1890, and 18.30 on the estimated population for 1892. Among the causes of death tuberculosis, with a rate of 22.88 per 10,000, stands foremost, pneumonia following with a rate of 21.56. The rate for influenza, which was epidemic during the winter, was 11.43 per 10,000, which is partly accounted for by the fatality of this disease at the extremes of life and the proportionately large number of the aged to the total population, due to the emigration of young men and women to the Western States.

The number of deaths from whooping-cough exceeded that from scarlet fever, a fact that lends emphasis to the comment that the former is a more serious disease than the general public supposes it to be.

—

The Human Element in Sex. Being a Medical Inquiry into the Relation of Sexual Physiology to Christian Morality. By Dr. Elizabeth Blackwell. New Edition. London: J. & A. Churchill, 1894.

This small book is, in the main, a plea for the instruction of parents in sexual physiology, as only through such knowledge can they appreciate their responsibilities as guardians of the young, and avert the evils arising from ignorance or pernicious teaching regarding the sexual faculty.

"It is the predominance of the mental or spiritual element in our nature," says the author, "which is the characteristic fact of human sex," a radical distinction between the sexual faculty in man and the brute creation greater than any resemblance between them. In virtue of this difference—of this human element—"sex in the human race is capable of great development toward good or evil," an important fact that bears a positive relation to the well-being of succeeding generations.

Chastity is a physiologic law imposed in the interests of society, a providential check on the blind, unrestrained use of the sexual impulse necessitated by our physiologic structure for the vigor and continuance of the race. It is an equal obligation of the sexes; other reasoning (based on erroneous knowledge—misapprehension of the equivalent functions of ovulation and spermation) implies inferiority in the male—less power of self-control and of self-adjustment than is possessed by the female.

—

The Royal Victoria Hospital, Montreal. First Annual Report, for the Year ending December 31, 1894.

The first annual report of the Royal Victoria Hospital, Montreal, which has just been received, presents several features of interest. In the first place, the secretary and the management are to be congratulated upon the clean, clear appearance of the pamphlet, and the medical staff upon the admirable arrangement of the statistical report. During the year 1570 patients were treated, with a death-rate of 5.9 per cent. The expenditure of the year was a little over $65,000, which seems to be an extremely reasonable amount, considering the extent of the hospital-plant.

The statistical report has evidently been prepared with great care, and in addition to the usual columns of the admitted and discharged there is a third noting the number of days in hospital.

It is interesting to note that on the medical side there were only two cases of appendicitis admitted, both of which were cured; while on the surgical side there were forty cases admitted. On turning to the table of operations one sees that thirty-six of the latter cases were operated upon, with three deaths.

Of typhoid fever eighty-four cases were admitted, seventy-two discharged cured, and only three deaths, a remarkably low percentage. It would be interesting to know if systematic hydrotherapy was employed.

We congratulate the management and the professional staff on the completion of the first year of what will doubtless prove a most beneficent work for the entire Dominion of Canada.

—

Syllabus of Gynecology, based on the American Text-book of Gynecology. By J. W. Long, M.D. Pp. 133. Philadelphia: W. B. Saunders. 1895. Price, $1.00.

Dr. Long's book is a tabulated synopsis of the *American Text-book of Gynecology*, interleaved for note-taking, and prepared with a three-fold object: First, to be used as lecture-notes; secondly, to enable the student more intelligently to follow and remember the lecture; and, finally, as a convenient reference for physicians. The book is well adapted to the purpose for which it was intended, but shows evidence of haste in its preparation. Thus we read of Hagar's colpoperineorrhaphy; dysmenorrhea is spelled with an *æ* at one place and an *e* at another; œdema is used throughout, while *c*eliotomy and gonnorhœa receive the preference; and colporraphy is spelled as here written. We are also told that the use of electricity in uterine fibroids is still *sub judice*. The book may be materially improved by the removal of such defects as those mentioned.

NEWS ITEMS.

Prof. Rudolph Leuckart.—It is proposed to celebrate the fiftieth anniversary of the accession of Prof. Leuckart to the doctorate, on December 13, 1895, by the erection of a marble bust of the distinguished zoölogist.

William W. Browning, A.M., M.D.—The degree of Master of Arts was conferred on Dr. W. W. Browning, of Brooklyn, by Yale College at its recent commencement.

Prof. Englisch has succeeded Prof. Dittel in the direction of the Third Surgical Clinic of the Vienna General Hospital.

For the James E. Reeves Fund.—We have received from Dr. G. L. Magruder, $1.

ORIGINAL ARTICLES.

THE PRESENT STATUS OF THE DIPHTHERIA-QUESTION.

BY HENRY W. BETTMANN, M.D.,
CURATOR AND MICROSCOPIST, CINCINNATI GENERAL HOSPITAL.

MUCH can be learned from a study of the present status of the diphtheria-question. What is more important, a proper direction may thereby be given to future work. It is strange how the minutiæ of diseases escape careful consideration until some special line of research calls for the most exact examination of all details. Future work on diphtheria can be made more rapidly productive of results when the questions to be solved are accurately outlined. Certain it is that the diphtheria-problem cannot be reduced to the same simple formula in man as in the lower animals. In the artificial diphtheria of animals the Loeffler bacillus is the exciting cause, the antitoxin is the neutralizing agent—and there the matter ends. In man, however, many etiologic factors remain yet to be solved.

The use of Loeffler's culture-serum for diagnostic purposes, though adapted to clinical ends, has led to scientific misconceptions. Throughout the recent literature we find the terms "pure culture" and "mixed infection" used haphazard. These terms lack scientific definiteness. No one knows exactly what "mixed infection" is, and there is reason to doubt if a "pure infection" ever occurs. Nothing can be more self-evident than that the question of mixed or pure infection cannot be solved by one culture-medium alone, especially if that medium is especially devised to favor the growth of one germ and retard the growth of others. To use Loeffler's culture-serum for diagnostic purposes is highly satisfactory; to use it as a basis of scientific differentiation is clearly irrational.

Silberschmidt[1] examined 91 cases of diphtheria with Loeffler's serum, bouillon, and glycerol-agar, and all but one showed the presence of streptococci or staphylococci. Those who work with glycerol-agar alone will sometimes fail to detect the Loeffler bacillus when it is present in the throat; and those who work with Loeffler's serum alone will fail to find other germs that could be demonstrated by other means.

Bernheim[2] has shown that if streptococci and Klebs-Loeffler bacilli are inoculated in the same tube the streptococci are retarded in development. Bernheim by the use of glucose-bouillon and Loeffler's serum demonstrated that none of his cases presented "pure infection."

In a recent examination of over 120 throat-cases I failed to find any that might be considered a "pure infection."

The term "mixed infection" is far from standing for anything definite. If every case in which streptococci or staphylococci are present at the site of infection is a case of mixed infection, then cases of pure diphtheria are rare indeed. The predominance of one germ over another cannot be made the basis of scientific discrimination, especially if only one culture-medium is used. In follicular tonsillitis staphylococci and streptococci are present. In a case of "mixed diphtheria" we should expect in addition to the symptoms due to the Klebs-Loeffler-bacillus those due to the streptococcus and the staphylococcus; but this is notoriously untrue, as the symptoms (fever, headache, backache) of follicular tonsillitis are usually more severe than those of diphtheria.

What is "mixed infection," and how can we tell that the cocci present in a diphtheric throat are playing any *rôle* in the disease? Certainly, to talk of the comparative value of the antitoxin in cases of pure and in those of mixed infection is thoroughly irrational, as we do not know what is pure infection and what is mixed infection. A prognosis cannot be made from the bacteriologic examination, as some cases die in which staphylococci predominate, others in which Klebs Loeffler bacilli predominate. It may be interesting to note here that Bernheim[1] has shown that if animals are inoculated with the filtrate of cultures of diphtheria-bacilli and streptococci, the disease runs a more violent and rapid course; if, however, a filtrate of cultures of staphylococci is used in large quantity the disease is milder than in cases of pure diphtheria.

The question of deciding the infectiousness of convalescent patients is not so easy as was supposed. When a pharyngeal culture fails to reveal the presence of virulent Klebs-Loeffler bacilli the patient is usually dismissed as no longer dangerous. Tezenas du Montcel[2] showed that when there is a nasal discharge the pharyngeal culture may repeatedly prove negative, and still virulent bacilli may persist in the

[1] Münchener medicin. Wochenschr., Feb. 26, 1895.
[2] Zeitschr. f. Hygiene, B. xviii, H. iii.

[1] Loc. cit. [2] La Province Méd., August 5, 1893.

nose from one to eight weeks. Sevestre et Méry[1] examined 18 cases from day to day in 1893. In one case non-virulent bacilli persisted in the pharynx several days; one month later the bacilli were found to have regained virulence and a sister of the patient was seized with the disease. In two other cases virulent bacilli were found fifteen days after recovery, although intermediate cultures revealed only non-virulent bacilli. In two other cases pharyngeal cultures were negative, though nasal cultures showed virulent bacilli, in one case up to the forty-ninth day. These researches prove that non-virulent bacilli may regain their virulence, and that an existing nasal discharge should not be overlooked in declaring convalescents contagion-free.

The relation of albuminuria and nephritis to diphtheria is another subject that requires clearing up. All writers have noted the great frequency of albuminuria in diphtheria, and most of them have used albuminuria and nephritis as interchangeable terms. Nothing has been made more clear by recent study than that in a large proportion of cases the albuminuria of diphtheria does not depend on nephritis. We are not justified in diagnosticating nephritis unless we find epithelium, casts, or blood in the urine. Anyone who takes the trouble to examine diphtheric urine microscopically will be surprised to find how often albuminuria may exist without the presence of renal elements in the urine. Fischer[2] reports 141 cases of albuminuria without casts. I have myself frequently examined the albuminous urine of diphtherics without finding evidence of nephritis. Schroeder[3] reports 44 cases of albuminuria, only 6 of which presented evidence of nephritis. The Stadt Physikat of Triest[4] reports 105 cases of diphtheria; 75 of these had albuminuria, but only one-half of these had casts in the urine. This rather startling clinical evidence is made more striking by post-mortem observations. Goodall[5] reports 30 cases of suppression of urine in diphtheria, leading to a fatal issue in 27 cases. The common characteristics of these cases were: Severe local disease; marked albuminuria; never hematuria or sediment in the urine; anuria more or less complete; frequent vomiting and cardiac failure. Post-mortem examination of the kidneys showed them to be usually normal to the naked eye in every respect. Ten cases were examined microscopically and only trivial changes found. Nothing can be more conclusive than that marked albuminuria and renal insufficiency may be due to causes outside of the kidneys themselves. F. Siegert[6] reports a series of 100 tracheotomized diphtheria-cases; 27 of these had albuminuria, but nephritis was found post-mortem only three times; 10 patients had from 0.5 to 6.0 per cent. of albumin in the urine *intra vitam;* very careful post-mortem examination failed to reveal the presence of nephritis.

In estimating the effect of the antitoxin on the kidneys, therefore, much more must be taken into account than the existence or the degree of albuminuria. In fact, a new subject is opened for investigation, and the albuminuria of diphtheria has yet to be explained. One thing seems fairly certain, viz., that the antitoxin exerts no harmful influence on the kidneys.

It is probable that the experiments of Mya[1] represent the truth of the matter, viz., that the antitoxin has no appreciable effect on heart, blood, or kidneys. This observer watched four children from eighteen months to six years of age. He kept them under very close observation for several days, noting pulse, diurnal temperature-variation, blood, and urine. Then he injected 30 c.cm. of the antitoxin, and noted the changes during the succeeding hours and days. The first child, aged six years, convalescent from measles, presented the following conditions for several days before inoculation: The erythrocytes numbered 5,160,000; the leukocytes 6916. The average quantity of urine for twenty-four hours was 660 c.cm.; the specific gravity was 1014; the urea equalled 14.25 gm.; there was present neither glucose nor albumin, but a trace of indican. The rectal temperature varied from 37.5° C. to 37.8° C. The injection of the antitoxin was followed in a few hours by a reduction of the erythrocytes to 3,541,666; an increase of the leukocytes to 9381. No variation was noted in pulse or temperature. The urine increased to 1280 c.cm. on the second day; the secretion was free from albumin, glucose, and urobilin. All of these variations were transitory, and in a few days the normal was regained. The results in the other three children were the same. The changes due to the antitoxin may be summarized as: 1. Transitory diminution of the red blood-corpuscles. 2. Slight leukocytosis. 3. Polyuria. 4. Slight increase in the excretion of urea.

That the oligocythemia was not due to destruction of corpuscles is proved by the absolute absence of urobilin from the urine. It was probably due to dilution of the blood from the lymph-channels, as also evidenced by the leukocytosis and polyuria.

These observations of Mya are very important, as they were conducted with great care. Moreover, they agree with other clinical observations. Albuminuria is present in a majority of cases of

diphtheria treated without the antitoxin, being variously estimated by Henoch, Baginsky, and Eberth, as occurring in from 50 to 60 per cent. of all cases. Schwalbe[1] reports 470 cases of diphtheria in the Friedrichshain Hospital before the antitoxin-period; albuminuria was found in 227, though examinations were made but once in each case. Kolisko[2] says that in 75 post-mortems of cases treated with the antitoxin the kidneys presented no deviation from kidneys seen before the antitoxin-period. Ganghofner,[3] in a most guarded paper, reports albuminuria, lasting any considerable time, as occurring in only 20 of 110 injected cases. Of 33 cases injected on the first or second day, none had severe albuminuria. In Cincinnati albuminuria occurs in nearly every severe case of diphtheria. I had the opportunity in March of making a curious observation of five children in two families, two of whom were treated with and three without the antitoxin. The cases all ran a mild course, but all suffered from rather marked albuminuria. The cases lay side by side in a hospital-ward. The appetite was good in all, and there was no pain, no edema, no morphotic elements in the urine; yet the albuminuria persisted in all, notwithstanding treatment for from two to three weeks. Authorities are almost unanimous in the belief that the antitoxin does not lead to increase in the proportion of albuminurics, some even noting a diminution.

Testimony on the subject of the heart is variable, the vast majority of writers noting no bad effects on the heart. Some few, among whom is Baginsky, believe that the heart is unfavorably affected. Mya observed absolutely no variation in the rate, rhythm, or tension of the pulse, as shown by sphygmographic tracings. Observations of the blood have yet to be made. Certain it is that fear of bad effects need cause no one to abstain from the use of the antitoxin.

It is yet impossible to determine the effects of the antitoxin on the paralysis of diphtheria. Exact figures are not available. The occurrence of paralysis varies in different epidemics and in different regions. In Berlin it is very common (Henoch); in Munich it is not often met with (Seitz); in Halle it is uncommon (v. Mering). It seems incredible that the use of the antitoxin should increase the proportion of cases attended with paralysis; clinical reports, on the other hand, seem to show that the proportion is not reduced. Heubner[4] reported paralysis in 7.4 per cent. of 207 cases treated with the antitoxin; C. Seitz[5] injected 74 cases on the first or second day of the disease, and encountered some very severe cases of paralysis. Hager[1] had 3 cases of paralysis among 20 under observation; Washburn[2] 6 among 48 survivors; Fischer 21 in 190 cases; Mya[3] 5 in 50 cases; Soltmann[4] only 4 among 76 recoveries; Germonig[5] only 8 in 290 survivors; Siegert[6] 33 in 100 tracheotomized cases; and so on through a long list. It is advisable to look over old records of the pre-antitoxin-period and strike a general average for each locality, and then to follow up all new cases with watchfulness. This will require years of attention, and this is destined to be one of the last problems connected with the subject to be solved.

When we come to the final question as to how far the antitoxin has reduced the mortality of diphtheria we enter upon a most perplexing field of inquiry. When all is said and done, the statistical method is the court of ultimate appeal; and yet just this method exposes us to a thousand errors. Here, too, it will be found profitable to seek the sources of error and eliminate them as far as possible from future research and summaries. Up to the end of January over 3000 reported cases had been collected, with a mortality of 20 per cent. (Heubner), and reports since that time have given us about the same results. On its face-value this seems to give us a marked reduction in mortality as compared with former times, and yet a critical estimate bids us withhold our judgment.

I should like to emphasize the following propositions:

1. Hospital-statistics considered by themselves are likely to be misleading. 2. Diphtheria treated under favorable conditions is not so fatal a disease (even in Europe) as is commonly supposed. 3. The bacterial criterion of diagnosis has a wide influence on the results achieved.

Regarding Hospital-statistics. Common observation teaches us that agitation of new remedies among the populace leads to a rapid influx of patients suffering from that disease to the centers of treatment. In 1890 the tuberculous world flocked to Berlin and to the hospitals for tuberculosis. During the past year hospitals have dealt with vastly more cases of diphtheria than heretofore. We are indebted to Gottstein, of Berlin,[7] for some brilliant observations on this score. He compares the admissions and deaths in the Berlin hospitals with the municipal cases and deaths during the past five

[7] Therapeutische Monatshefte, Jan. 1895, p. 33.

years. From September 30th to November 24th there died of diphtheria in the Berlin hospitals, in 1890, 131 cases; in 1891, 124 cases; in 1892, 178 cases; in 1893, 197 cases; and in 1894 (antitoxin-period), 131 cases; the admissions, however, during this period increased from 328 in 1890 to 712 in 1894. The mortality in Berlin from diphtheria is less than half the mortality in the Berlin hospitals; *i. e.*, the severest cases are sent to the hospitals. Now if all of the cases in Berlin were sent to the hospitals the mortality would, without any change of treatment, fall, *eo ipso*, 50 per cent.

This is just what happened in the autumn of 1894. The number of admissions more than doubled and the mortality sank 50 per cent. The total mortality, however, was not thereby reduced, and as many cases died in 1894 as in 1890, only the place of their dying was changed. In 1890 there were 1591 deaths from diphtheria in Berlin, of which 682 (or 43 per cent.) occurred in the hospitals; in 1894, from January 1st to November 24th, there were 1281 deaths in Berlin, of which 737 (or 57.5 per cent.) occurred in the hospitals. Gottstein concludes with complete justification as follows: 1. The death-rate in hospitals was reduced 50 per cent., because twice as many cases were admitted. 2. The total mortality in hospitals in 1894 (to November 24th) was already larger than for 1890 or 1891. 3. The total mortality in the hospitals *and* the city was not at all reduced.

This able analysis explains the apparent benefit of the antitoxin in many other hospitals, and we may justly doubt the value of the statistics of any hospital that has suddenly experienced a large increment of patients.

With very few exceptions it is true that the mortality from diphtheria in cities at large is very much less than in the diphtheria-hospitals, and hence any influx from the city to the hospital would of itself lower the mortality-percentage of the latter. This is exemplified in the reports from Trieste.[1] In 1893, 110 cases were treated in the hospital and 52.7 per cent. died; in the first eight months of 1894, 149 cases were treated and 46 per cent. died. Now came the antitoxin-period; in the next five months 362 cases (!) were admitted and the mortality was naturally reduced to 20 per cent. Hahn reports from the Friedrichshain Hospital that though the number of cases in 1894 was very much increased, the total mortality in the hospital was not reduced, but only the percentage. Thus we see that hospital-statistics *per se* are unreliable, and we should know in every case the number of cases treated as compared with the total number in the respective city.

Diphtheria treated under favorable conditions is not so fatal a disease as is commonly supposed. At the Congress of Internal Medicine, recently held in Munich,[1] Baginsky said that his contemplation of diphtheria in former years was among the most gloomy of all his experiences: "In the diphtheric pavilion I gained the impression that we were absolutely helpless in dealing with diphtheria, and that nursing did more than medicines." All this sounds dramatic, but we must remember that at the Munich Congress Baginsky was pleading the cause of the antitoxin. In 1891 his contemplations were not so gloomy, nor his results so bad as he has since depicted them. In his *Arbeiten aus dem Kaiser u. Kaiserin Friedrich Kinderkrankenhause*,[2] published in October, 1891, he thus sums up the work of the diphtheria-pavilion for the first year of the hospital's existence: 244 cases were treated; the mortality was 40 per cent.; thirty-seven of these cases were admitted with far-advanced septic and gangrenous diphtheria and died soon after admission. "Subtracting these cases," says Baginsky (p. 246), "but including a larger number of those that were tracheotomized, we had a mortality of 23.1 per cent., a result in diphtheria with which we ought to be very well satisfied." In his recent book he reports 527 cases treated with the antitoxin, with a mortality of 15.6 per cent.

Much stress is laid by the upholders of the antitoxin on the fact that the sooner the cases are injected the better the prognosis; and the brilliant achievements of the antitoxin in this particular are above dispute. It is, perhaps, not useless to call attention to the fact that before the antitoxin-period the prognosis was good in cases brought early for treatment.

F. Siegert[3] gives his results in the treatment of diphtheria without the antitoxin in the children's clinic at Strasburg. He cites in detail 100 cases that required tracheotomy—hence all severe cases. Six were received on the first day of the disease—none died; ten on the second day—two died. After the second day the mortality ranged from 31 to 53 per cent. Siegert urges further that fatal complications do not arise, as a rule, until after the fourth day, and that, therefore, if cases are treated early the mortality will be reduced *eo ipso*. Of fifty fatal cases in his clinic, there died on the first three days of the disease none; on the fourth day five; on the fifth day eight, etc. Dangerous symptoms do not arise early; parents wait until death seems imminent and then hurry their children to the hospital. During the antitoxin-period they take them early, and hence the percentage of recoveries is greater.

[2] Stuttgart: Ferdinand Enke.

[3] Therapeutische Monatshefte, March, 1895, pp. 118 *et seq.*

Ritter[1] states that in the two years preceding the use of the antitoxin he lost no case of pharyngeal diphtheria that was brought early for treatment, although he had had altogether ninety-one cases.

Baginsky, Kossel, Ehrlich, and others emphasize the fact that after the injection of the antitoxin the membrane never spreads into the larynx. Ganghofner,[2] however, in an article friendly to antitoxin, cites his pharyngeal cases during 1893, and finds that in only two cases did the membrane spread to the larynx after treatment was instituted. The mortality among these pharyngeal cases was only 15.8 per cent.

We learn from all these observations that diphtheria treated promptly under favorable conditions (hospital-hygiene, good nursing, food, and air) is by no means so fatal as we are taught to suppose, but that even in the pre-antitoxin-days the mortality was great only among neglected or improperly situated patients. In private practice, in Cincinnati, at least, the percentage of fatal cases is small; the mortality ranges here from 19 per cent. (in 1891) to 33 per cent. (in 1888), but the death-rate among the upper classes is very much less.

It is not true, as was first supposed, that all cases treated on the first or second day with the antitoxin will recover. Ganghofner had two cases that were injected on the second day to prove fatal; Heubner[3] reports failure in a few cases injected on the second or third day. Kohts[4] injected a case on the second day; twenty-four hours afterward new and extensive membranes formed. In another case, injected on the second day, the larynx became involved later, and tracheotomy was required. In the Trieste hospital five cases died, though injected on the second day.

Soltmann[5] had thirteen deaths among eighty-nine cases; six of the fatal cases were injected during the first four days of the disease; and in thirteen cases the membranes descended to the pulmonary alveoli, notwithstanding the antitoxin.

Vierordt[6] reports eight deaths among fifty-five patients. Two of the fatal cases were injected on the second day and two on the third. Ritter details the following history: He saw a strong child, aged three years, that had been taken sick only a few hours before; on both tonsils circumscribed patches appeared; the temperature was 39.7°, the pulse between 110 and 120. Behring's antitoxin No. 3 was used. The membranes nevertheless spread, the larynx was invaded, tracheotomy was refused, and the child died on the sixth day.

We are compelled to admit that the antitoxin fails to cure in a certain proportion of cases, notwithstanding the fact that all other conditions are favorable.

Finally, a few words are in order regarding the effect of the bacterial diagnosis on hospital-statistics. Formerly, at least in American cities, though all the fatal cases were reported, many mild cases were not. Now, that bacterial diagnosis and municipal supervision render diphtheria-cases in a measure public property, many more cases will be brought to the notice of health-officers than formerly, and the mortality-rate will seem to sink. This is prettily illustrated in the recent health-report of Boston for the year 1894. Boston has not only a Bureau of Bacteriology, but it also has an army of school-inspectors to examine school-children. With these combined means an enormous number of cases of diphtheria are ferreted out, cases that formerly would have been called simple sore-throat. This statement is made in the report itself. Thus in 1894 Boston had 3019 cases of diphtheria. The greatest number of cases any previous year was 1814. We would expect from this an enormous reduction in the mortality, but find that the mortality (27.06 per cent.) is but slightly less than in preceding years—and yet the Boston authorities congratulate themselves on having reduced the rate of mortality by means of the antitoxin. They have simply reduced the rate by means of bacterial diagnosis and school-inspection, while the absolute mortality is far in excess of former years.

Enough has been written to show that the questions concerning diphtheria and the antitoxin are still in their infancy, instead of nearing solution. It is well to know the pitfalls that are in the way of our attaining the truth.

A CONTRIBUTION TO THE STUDY OF DEAF-MUTISM.[1]

By ARTHUR AMES BLISS, A.M., M.D.,
of Philadelphia;
Laryngologist to the German Hospital; Laryngologist and Aurist to the Pennsylvania Institution for the Deaf and Dumb; Fellow of the American Laryngological Association, of the College of Physicians, Philadelphia, etc.

The subject of deaf-mutism is one that does not appeal very strongly to the interest of the busy general practitioner, or, perhaps, even to the aurist. We think of the totally deaf as a class of individuals whose condition has removed them beyond the pale of aural treatment—an incurable class, to be relegated, if still young in years, to the attention of teachers in institutions for training in vocalization, as having passed beyond the range of the aurist's work. Clinical experience has shown clearly that,

[1] Read before the Medical Society of the State of Pennsylvania, May 24, 1895.

when total deafness has been found to exist, or when in mutes the degree of hearing is reduced to a vague sense of sound, the best interests of the child are considered when it is transferred to the care of oral teachers.

The questions in connection with deaf-mutism, however, that cannot but have interest for the physician, are those relating to the prevention of loss of hearing in early childhood. Examinations of deaf-mutes made by Holger Mygind, and others (including some observations of my own), show undoubtedly that strictly congenital deafness is a far from common cause for failure in acquiring speech. By congenital deafness I mean the existence of abnormalities within the tract of hearing that have appeared during the development of the fetus. That such conditions can exist has been proved by post-mortem examination, and there are in most institutions for the deaf and dumb instances of children that show such abnormalities in the external ears and in the contour of the skull that we can, with a fair degree of reason, believe that there have been corresponding failures or errors of development within the sound-perceiving apparatus.

It has been a rather common practice to classify all children that have never spoken, and that have never given signs of having heard, as congenital deaf mutes; but, considering the great number of conditions attending many forms of disease that may attack the infant in the first few months of life, and that may tend to involve the ears in an inflammatory process, it seems to me that very many elements of doubt must be cleared away before we can say definitely that a given case of deaf-mutism is congenital. In other words, in by far the majority of deaf mutes there were opportunities given the care-takers of the children for preserving the hearing, or for lessening the consequences of destructive processes that were annihilating one of the five senses. Thus coryza, the exanthemata, syphilis, asthenia after wasting diseases, may, in very early infancy, rapidly destroy the delicate aural tissues, while destruction is in progress, also, in other tracts of the body. This latter process may be noted and receive full attention from the children's care-takers, while the process within the ear is unnoted or ignored. The child recovers, and its disease leaves no impression on the organs whose lesions caused most anxiety to the medical attendant and to the family, yet the unnoticed aural complication has left permanent, perhaps total, deafness.

I have seen a child, about thirteen months of age, that had suffered for weeks, during a hot summer, from enterocolitis. Little attention was paid to anything above the diaphragm. During the active stage of the illness the child had at frequent intervals given vent to what has been termed the "hydrocephalic cry," but which is not uncommon in young children suffering from pain within the ears. The child pulled feebly at the left auricle and pressed its head against the pillow. Eventually, a slight discharge from the meatus of this ear appeared, but soon ceased, to be followed by a swelling over the mastoid process of the same side. The aural complication had now progressed for two weeks without attracting attention from the abdomen. Sweating, chills, and pyemic symptoms had been manifest, but not until a mastoid abscess bulged the left ear out like a horn from the infant's head did the attendants decide that the ear required any special care. A grave, destructive process, lessening the child's hearing, perhaps its power of speech for life, had progressed under the eyes of intelligent parents, nurse, and doctor. How frequent may not such instances be in the crowded, undisciplined homes of those whose children form the great number of our deaf mute pupils, and whose statements as to the origin of deafness are accepted and furnish the data for statistics regarding the causes of deaf-mutism! No objective symptoms may occur that would be noted by such persons; yet an active destructive process may have caused total deafness, and the parents report that the child was "born deaf."

In a series of pupils, numbering 546, examined at the Pennsylvania Institution for the Deaf and Dumb, it will be noted how many of the diseases charged with causing the deaf-mutism are common to childhood or to early infancy:

Scarlet fever	78
Cerebro-spinal meningitis	44
Meningitis	39
Measles	19
"Colds"	15
Convulsions	12
Traumatism	14
Otitis media	11
Typhoid fever	8
Spinal meningitis	8
Pneumonia	4
Catarrhal fever	4
Teething	3
"Malaria"	3
Black fever (?)	3
Cholera infantum	3
Diphtheria	2
Enteritis	2
Whooping-cough	2
Rachitis	1
Smallpox	1
Shock	1
Mumps	1
Bronchitis	1
Sunstroke	1
Croup	1
Eczema	1
Unrecorded	8
Unknown cause	56
"Deaf from birth"	200

The cases marked as "deaf from birth," 200 in number, would doubtless be greatly lessened if the

parents had been more accurate in their reports. Ignorance and want of intelligence may account for lack of more exact data.

A study of the conditions revealed by an examination of the ears of the 546 pupils is very suggestive of the results of destructive processes that may have been, and probably were, at first, limited to the sound-conducting apparatus. These lesions consist (1) of a sclerosing, non-suppurative process affecting, primarily, the sound-conducting apparatus, and resulting in immobilization of its various parts; (2) of extensive destruction of the tympanic contents by a suppurative process, in many cases still active, which has destroyed the middle ear, and, probably, portions of the inner ear also, while, in some instances, it has caused exfoliation of the ossicles, destruction of the mucous lining of the tympanum, denudation and necrosis of its bony walls, and the development of cholesteatoma. As one case not infrequently presented several lesions, it will be understood why the total number of cases reported exceeds the number of individuals examined.

1. Otitis media sclerotica, the drumheads being feebly movable	191
2. Otitis media sclerotica, with adherent and immovable drumheads	150
3. Engorgement of the manubrial vessels, the drumheads being pinkish, suggestive of an active catarrhal inflammation of the mucous membrane of the tympanum	10
4. Calcareous deposits in the drumhead	16
5. Perforation of the drumhead, with active suppuration	46
6. Cicatrized perforations	55
7. Impactions of cerumen	57
8. Atresia of the auditory meatus	2
9. Undeveloped auricles, with absence of the external auditory canal	1
10. Foreign bodies in the external auditory canal	7
11. Desquamative inflammation of the external auditory canal	4
12. Drumheads appearing normal	51

It will appear from this list that the great majority of these conditions suggest a comparatively slow but destructive process, either with or without suppuration, tending to cause sclerosis by fibrous or bony changes within the sound-conducting apparatus. In other words, there are few of these conditions that might not have yielded to judicious treatment employed in the early stages of the aural disease. At the same time we must not be misled into the error of supposing that each of these conditions noted represents the cause of the total deafness in every case in which it has been noted. The abnormalities of the posterior nares and pharynx in many of the pupils in this series indicate the possibility that middle-ear sclerosis may have developed gradually, in some instances, as a result of such nasal and pharyngeal disease, subsequent to a destructive process within the sound-perceiving apparatus that had itself already destroyed the sense of hearing. The aural lesions noted, however, cannot be disregarded, even considering this possibility.

The ages at which deafness is stated to have developed is of considerable interest:

At birth	200
Under one year old	48
From one to two years old	84
From two to three years old	62
From three to four years old	56
From five years old and over	55
Uncertain	41

I have already referred to the uncertainty of a diagnosis of deafness at birth, while deafness sufficient to cause failure in acquiring speech may not be noticed until the second year of childhood. Considering this fact, and considering, also, the character and chronicity of the aural diseases suggested by the lesions observed in pupils whose deafness is dated from birth to the second year of childhood, I feel safe in grouping these periods together, making 332 pupils out of the total, 546, whose aural disease developed in the years before the rudiments of speech are acquired. At this early age the child may be the victim, as well as the ward, of its care-takers. It can but imperfectly call their attention to many grave symptoms, and its feeble efforts at so doing may be unnoticed or ignored. We must exclude from this number the instances in which, from the personal and family history, as well as from the objective symptoms, it is reasonable to believe that deaf-mutism was indeed congenital. I do not feel that our tests, at present, enable me to give the number of this latter class of pupils with any degree of certainty. The indications, as judged from the conditions found in the ears of the entire series of 546 pupils, favor the idea of deafness developed subsequent to birth, and with otitis media, resulting from many different processes, as a direct cause.

Consanguinity of parents has been found by observers to be one of the causes of deaf-mutism. In thirty-one instances among our series of 546 pupils, the parents were stated to be blood-relations. This is not a large percentage, yet it can scarcely be passed by unnoticed. The influence exerted by consanguinity of parents as a causative element in producing deaf-mutism in their children is a subject involved in much obscurity. Where others have failed in explanation, I do not even attempt to do better. It must be commonly noted, however, by all physicians that blood-relationship in parents whose family has a strong predisposition to certain diseases of the pulmonary or nervous system, or to syphilis in its varying degrees of activity, is prone to result in the birth of children presenting many abnormalities of anatomic structure and physiologic function. In such weaklings the structures of

the ear are certainly no more proof against divergence from the normal than are the parts of the cerebro-spinal tract or the lymphatic system. Even in robust subjects, the tissues of the ear yield readily to inflammation; much more readily must they yield in these strumous, feebly recuperating children of the class to which I refer.

It is a question if the blood-relationship of absolutely robust parents, members of a sound, healthy family, would have a sinister influence upon the physical health of their children or be in any way a factor in producing deaf-mutism. The exaggeration of vicious physical defects, or of a tendency to grave disease by the intermarriage of unhealthy relatives is certainly a very potent factor in causing deaf-mutism. A tendency to aural disease, or to catarrhal inflammation of the upper respiratory tract and ear, seems to be not uncommon in the families of deaf mutes. One-fifth of the entire series of pupils studied belonged to families having other deaf mutes among their members. In fifteen instances the parents were themselves deaf mutes. In 123 instances other children of the same family, cousins, aunts, or uncles, were partially or totally deaf or were also mutes.

Among our series of cases are a few very startling instances of the general distribution of deaf-mutism through a family. In these an entire family may form, as it were, a community of deaf mutes. The existence of deaf-mutism among the near relatives of about one-fifth of the pupils in our series sufficiently indicates that a tendency to destructive diseases within the ear is common to certain families. In such instances it would appear that there must exist some inherent weakness, by reason of which the tissues fail to resist the influences of disease to a greater degree than is the case with more nearly normal subjects. The nature of such physical taint can scarcely be analyzed. It is probably very multiform in character, and may arise from any conditions that have made a deep impress upon the vital centers that control nutrition and growth. Syphilis, extreme alcoholism and debauchery, years of great poverty, with mental and physical suffering upon the part of a parental pair, may account for a progeny of defective men and women, among whom deaf-mutism claims a few victims, while struma, pulmonary tuberculosis, locomotor ataxia, rheumatoid arthritis, idiocy, epilepsy, and insanity may have a greater number of subjects. In other words, deaf-mutism is only one of the phases of physical degeneration that may appear in members of a physically degenerate race. It is to such individuals that we may look with reason for instances of true congenital deaf-mutism, especially if taints of disease are concentrated by the intermarriage of members of such stock.

The lessons to be learned from these statistics, and those of other observers, bear relation mainly to the prevention of deafness in infancy and early childhood. We have seen that, excluding the unfortunate victims of inherited weakness and disease, to whom the congenital deaf mutes probably belong as a class, we have large groups of individuals whose total deafness (and resulting mutism) has developed at an early age, and was apparently of such nature in the beginning as to have allowed of cure had the aural conditions been recognized in time and treated judiciously.

The best methods of treatment are made manifest when we note the changes within the fauces and posterior nares of deaf-mute pupils. This ground has been gone over quite thoroughly by several observers, including myself, and it is not necessary to repeat the details. Suffice it to say that the investigations of observers who have given attention to the upper respiratory tract and ears of deaf mutes show that hypertrophied and diseased tonsils and hypertrophy of the lymphoid tissue within the post-nasal space are exceedingly common conditions. We know how commonly they exist in children whose hearing is still normal, and how intimately they are associated with catarrh of the middle ear.

Such conditions, causing mouth-breathing, want of drainage of the excessive mucous or muco-purulent discharge resulting from the attendant catarrhal rhinitis, causing also pressure upon or closure of the Eustachian tubes, must be removed and the parts rendered as nearly normal as possible. Such measures are of special importance in children whose family history indicates a tendency upon the part of their parents or other relatives to contract aural diseases, with the development of grave deafness. Otitis media, as a complication arising during the course of any illness in early childhood, requires early diagnosis and careful after-treatment. With the relief of the acute symptoms and the distressing pain, the treatment does not end. An uncared-for, acute, non-syphilitic inflammation may drift on into a slow, progressive, sclerosing process, binding the mobile parts of the middle ear in fibrous or bony union, and extending onward into the labyrinth, while an acute suppuration, with rupture of the drumhead, may continue until a chronic otorrhea has been established, with all its attendant dangers to the hearing-power, to the health, and even to the life of the child.

The strange trust in time and circumstance, or, we might say, in fate, that expresses itself in the belief that otorrhea must not be cured, that aural symptoms will be "outgrown," that otitis media in subacute form is a natural aftermath of measles and scarlatina, and that some supernatural influence that brought it about will also lead to its cure while we look on, is not a rational trust in Providence; nor can the doctor safely congratulate himself that the "con-

founded ear-trouble" is, for him as well as for his patient, at an end when "the gathering in the head" has broken. With the general practitioner rest the care and responsibility for the preventive treatment during the illnesses of early childhood. He should be on the lookout for aural symptoms; should know the simple means at hand for their treatment, rather than have recourse to olive-oil, almond-oil, Harlem-oil, catfish-oil, kerosene-oil, all served hot or cold, with or without laudanum, as the child's grandmother may desire. A plug of raw onion need not be wedged into the affected ear, and yet the doctor may do his duty. The teachings of the professor of aural and rhino-laryngeal diseases, now, after many years of stupid opposition, a recognized member of the faculties of many of our medical schools, will tell of better things, and the physician in any city or large town can call an aural surgeon to his aid if the simpler methods fail him.

THE EARLY RECOGNITION AND THE CLIMATIC TREATMENT OF PULMONARY TUBERCULOSIS.[1]

By H. B. MOORE, M.D.,
of Colorado Springs, Col.

Each year's added experience with the high-altitude treatment of pulmonary tuberculosis impresses me freshly with the idea that certain very elementary facts relating to this very valuable therapeutic method, although often detailed by interested students of the subject, are constantly lost sight of by physicians prescribing this mode of treatment. The most important of these relates to an early recognition of the true nature of the case, so that the altitude-treatment may be instituted at once, and to the desirability of a more or less prolonged residence at the high altitude. Disregard of reasonable forethought in these particulars, more especially the first point, leads to great disappointment on the part of patients and friends and brings undeserved disrepute upon the treatment. I am willing to admit that some of the blame for this should rest upon the shoulders of too enthusiastic admirers. A goodly portion of it, however, belongs properly to that large body of practitioners who no sooner read of a new cure than they proceed to try it indiscriminately upon every case of the malady coming under their observation.

What is true of other diseases and their medical treatment is also true of the climatic therapeutics of pulmonary tuberculosis. It is far from wise to send every such case to Colorado to try the high-altitude treatment. The prospect for an arrest or cure of this disease diminishes very rapidly with its advance, and what has been a most favorable case may soon become inappropriate for this climate. Prophylaxis is always better than cure, and the family physician, seeing a rapidly growing boy or girl with imperfect chest-development, in a family predisposed to tuberculosis, can often avert a catastrophe by sending the child to a high altitude. The outdoor life, sunshine, and rarefied air of these regions are the most rational and perfect preventives of which one can conceive. Such cases are common in the experience of all physicians, and a practical recognition of the truth of this statement will lead to most gratifying results.

When too late for prophylaxis, and the disease is actually in progress, it seems to me (and my experience in this line has been such as to create strong convictions on the subject) almost criminal to keep the patient at home trying cough-medicines, creosote, guaiacol, cod-liver oil, hypophosphites, etc., during that valuable time, often so short, when climatic treatment is really capable of rendering radical assistance in the struggle with the invading enemy; but, alas, often, one might say usually, the patient is kept at home until the vital powers are weakened by advanced disease, and then, finally, it is decided to send the patient somewhere for his health. Is this reasonable, and can anyone who has the slightest grasp of the subject imagine, for an instant, that any climate will materially help a considerable percentage of cases of this kind? The system is already poisoned with the products of suppuration, and each day finds the cells less able to cope successfully with the already existing disease-area, to say nothing of its spread. This phlegmatic conception and management of tuberculosis is not rational and can never succeed.

One must have a sharp, clear-cut appreciation of the fact that a great danger menaces every individual whose tissues have become the site of the slightest degree of this form of bacterial invasion, and that, although some subjects are found to possess a remarkable degree of tolerance for the disease, as a rule the existence of any considerable amount of tuberculous tissue in the lungs constitutes a handicap too great for Nature to oppose successfully.

One error probably oftener fallen into than any other, even by physicians, is the idea that a person who looks well, or fairly so, cannot have tuberculosis. They cannot harmonize the appearance of an apparently healthy person before them with their conception of the pale and wan tuberculous patient, and forget that tuberculosis is an infective disease, which, like other diseases, has a beginning as well as an end, and if the symptoms are suspicious they think their science is at fault and call the disease "bronchitis" or a "cold that lingers," instead of by its right name. It would be interesting to know when, in the opinion of a large number of our professional brethren, these ailments ceased and

[1] Read before meeting of the American Climatological Association, Hot Springs, Va., June 13, 1895.

actual tuberculosis began. I have had the misfortune to see large numbers of self-deceived, or doctor-deceived, human beings with tuberculous cavities, hectic fever, etc., arrive in Colorado Springs as cases of "bronchitis," "protracted cold," etc., and die in due time. On the other hand, it is a real satisfaction to examine some of the patients sent to Colorado by men thoroughly conversant with the subject, who make an early diagnosis and act on it at once. As a case in point, of which I am glad to say there are many, that of a young man, already becoming well known in our own profession, comes to mind. He had been an athlete in college, and on arrival in Colorado Springs was a picture of healthy vigor, broad, full-chested, and with a good, healthy color; yet a little suspicious cough existed and examination of the chest revealed beginning slight trouble at an apex, and the sputum-examination showed quite numerous tubercle-bacilli.

Cases in which the tuberculous infection is discovered early, and there is scarcely more than a little infiltration at the seat of invasion, are ideal, and may be taken as models of what we should strive after. Often Nature comes to our aid and declares, by means of a small hemorrhage or a slight spitting of blood, that tuberculous invasion has occurred at some little point in a person who has not previously coughed or been unwell in any way. Such an occurrence, although very alarming to the patient, is really a most fortunate one if properly interpreted and acted upon by the physician. Very often, however, the doctor discovers some point in the throat (usually) or the bronchial tubes the seat of alleged congestion, which he assures the patient caused the bleeding, and encourages the latter not to be alarmed, and so the probably valuable significance of the warning is lost and not thought of again until its repetition, or warnings of another character throw unpleasant light on the subject.

It may be asked with propriety whether the very early cases are the only ones that it is wise to send to a high altitude, and whether conditions so efficacious in prophylaxis and in the early stage of the developed disease are without efficacy in cases that are further advanced on first seeking advice as to the advisability of a change of climate. The reply to this question would be that the high-altitude treatment is the treatment suited especially to the earlier manifestations of the disease, the subjects of which still retain a large amount of their accustomed vigor and are able to avail themselves fully of the advantages of outdoor life in mountainous climates, which, from the very nature of things, are not very equable and which require a considerable amount of hardiness to withstand temperature-changes readily perceived by delicate anemics and subjects of hectic fever. At the same time every physician with experience in elevated regions can recall many cases presenting relatively extensive areas of disease in subjects possessing a considerable degree of tolerance for the disease and free from fever, who thrive in these regions and live many years.

Actual cure, however, is rare in these cases, the disease being merely arrested and liable to begin afresh on return to damp, sea-level climates. A very extensive area of even inactive disease would constitute a decided contra-indication to the high-altitude treatment, as a considerable amount of good healthy breathing-space is necessary for a patient to obtain the requisite amount of oxygen in a rarefied atmosphere. It is rarely wise to send active febrile cases advanced beyond the first stage to a high altitude. The deeper breathing required and the exciting character of the climate are very likely to promote destruction of existing consolidation and increase fever. Many such cases are seen in Colorado, in which, so far from being aided, the end is undoubtedly hastened.

As regards the other point to which I wish to call particular attention, viz., the necessity of a more or less prolonged residence at high altitudes, it is a serious error to give a patient going to Colorado on account of tuberculosis the idea that he is simply to go there for "two or three months," or "to spend the winter." It is very rarely that expectations of this sort can lead to anything but disappointment, as the disease is of such an essentially chronic character that this length of time is scarcely more than sufficient to furnish an idea as to the probable efficacy of the climate in an individual case.

Right here arises a question that it is often difficult to answer, viz., when is a patient cured of pulmonary tuberculosis and when is the disease only arrested and completely inactive? and yet it is, to the last degree, important for the patient to have this question answered correctly if he wants to return home. Some might say that a case may be looked upon as cured when the cough and expectoration have ceased entirely, when râles have disappeared from the chest, and the weight and general bodily functions have become normal; but it is a matter of every-day experience that under such conditions the patient frequently again begins to expectorate bacilli-laden sputa and to exhibit all the symptoms of renewed activity, showing that the disease was not cured and that the tissues had constantly contained live bacilli and larger or smaller areas of tubercle ready to soften at the proper time. It seems, therefore, as a rule, much wiser for the physician at home to be very conservative upon this point and to instil into the patient's mind, from the first, the idea that the contemplated change of climate, if found on trial to meet the patient's needs, must be a long and perhaps permanent one. If the patient hears this for the first time from his

new physician after leaving home, he is naturally surprised at the lack of accord between this advice and what he had been led to believe previously, and feels home-sick and unprepared for so radical a change in his plans.

The desirability of the change of climate being very long or permanent is especially manifest when the patient is right in the midst of what might be called the most vulnerable age; when physique and family tendencies all indicate a subject of pronounced susceptibilities. Under these circumstances a premature return home after arrest or cure (?) might lead to a fatal relapse. Colorado Springs has to-day hundreds of citizens who have lived here for years with a good practical degree of health, enjoying their share of the activities and pleasures of life, and yet they are not cured of their tuberculosis and could not return to their former homes with safety. Many others have been completely cured and could live anywhere, but remain here from choice and the growth of local interests.

With respect to this point of prolonged residence our American high-altitudes in Colorado possess most conspicuous advantages over high-altitude resorts abroad, like Davos Platz, St. Moritz, etc., which are purely and simply health-resorts, offering no opportunities for occupation to those who need it and having no permanent society or home-life. In short, a young tuberculous person who has been sent sufficiently early in the disease to Colorado soon finds that he has not been consigned to a health-resort for life, but that he has simply changed his residence to another portion of the country filled with communities with many attractions, where work and a career still await him. It must not be inferred from these statements that Colorado has more positions than people to fill them or that it is especially easy to get remunerative employment, for such is not the case. On the contrary, the unemployed poor are found here as everywhere; but it is meant that talent and ability in all lines can find scope for their exercise here as promising as elsewhere, now, and with an encouraging prospect for future growth, often absent in the Eastern States. The lot of the very poor, who are at the same time ill, is a hard one anywhere, and must remain so until means are devised by the State or by individuals to relieve this most distressing form of need.

PENETRATING WOUNDS OF THE EYEBALL.[1]

By CASEY A. WOOD, M.D.,
of Chicago.

The responsibility assumed by the surgeon who undertakes the care of an eye whose envelops have been penetrated or ruptured is greatly increased by the fact that not only the vision of the injured eye, but that of the second eye may be at stake. The dreadful possibility of sympathetic or migratory ophthalmia, as it is more properly called, should always be borne in mind. This disease runs such a chronic and painful course, and is so disastrous in its effects, that when once encountered it is never forgotten. The unfortunate subject of it must wait during long weary months of pain and semi-blindness before his medical attendant can assure him either that he will eventually retain some vision in the uninjured eye, or that the injured eye, as sometimes happens, may be the more useful organ. It becomes, indeed, a question as to how long the emigrated micro-organisms, which are the essential agents in producing the lesions, will continue to multiply and poison the delicate structures within the second eye.

It is not my purpose to enter upon a discussion of certain theories respecting the pathology of ophthalmia migratoria, but rather to indicate, as well as I can, some of the principles commonly regarded in dealing with certain ocular injuries, and to illustrate these with some cases that have come under my own observation.

First of all, ocular traumatisms may be empirically, and, I think, usefully and practically, divided into three classes: (1st) those that are serious or not, from the standpoint of sight only, in which we are mostly concerned in asking whether or not the patient is likely to have useful vision in the injured organ; (2d) those that threaten the integrity of the second eye, quite apart from the fate of the injured eye, whose vision may at the time be fairly useful; here the eventual vision of the injured eye must be subordinated to the protection of the fellow-organ; (3d) those cases, probably the most numerous, in which sight is destroyed in the injured eye, and anxiety may be felt in respect to the vision of the other eye.

I wish first of all to report the histories of three cases that fairly belong to the first class:

In the summer of 1890 I was called in consultation with Dr. Greenfield, of Chicago, to see a young man who, in a drunken affray, had been stabbed in the left eye. The point of the knife had entered the cornea at its scleral margin on one side, had cut into the iris and lens, and had emerged at about a corresponding point on the opposite corneal border. The torn iris, with pieces of lens-matter, presented in the wound, the shallow anterior chamber being filled with blood. We decided to try to save the eye; thoroughly irrigated the sac with 1:5000 mercuric chlorid in a saturated solution of boric acid, carefully removed all the presenting lens-matter, blood, etc.; applied an antiseptic bandage; and were rewarded with having the corneal wound heal promptly and smoothly. There remained several posterior and anterior synechiæ, it is true,

[1] Read before the Illinois State Medical Society, May, 1895.

and the vision did not amount to much more than finger-counting, but the organ, even in this state, was undoubtedly better than an artificial eye.

Another case was even more satisfactory :

A child, aged four years, in the summer of 1892 fell from his chair while eating at table, and in doing so knocked down a glass bottle standing at his side. A piece of the broken glass cut through the upper lid and penetrated the sclerotic at about the equator, making a jagged wound about a centimeter long. The eye was carefully cleansed, and under chloroform a projecting bead of vitreous was snipped off; the edges of the conjunctival wound were carefully sutured, the lesion of the lid was looked after, and a protective bandage applied. The wound healed nicely and there was no symblepharon. To-day the patient can read fine print and has nearly normal distant vision with the injured eye. There is, of course, a peripheral defect in the visual field, and with the ophthalmoscope some vitreous opacities may be made out, as well as the site of the injury to the choroid and retina, which is marked by a mass of pigment.

Dr. Cory referred to me last March the following case :

A boy, aged eleven years, was hit in the left eye with a splinter of glass from a window through which a stone had been thrown. I saw him on the morning following the accident. He did not complain of pain, and there was very little blood on the bandage that covered the eye. The cornea, iris, and lens were the seat of an irregularly horizontal wound. The sclero-corneal junction was not affected. There was prolapse of iris into but not through the corneal incision. The lens had come forward into the empty anterior chamber: V. L. = p. l. Treatment consisted in careful antisepsis and asepsis, and the use of an ointment of atropin. The result was quite gratifying. The corneal wound healed very rapidly; there was no incarceration of the iris; and the lens underwent almost total absorption. There never was more than a slight pericorneal injection.

In none of these cases has there developed any sign of sympathetic ophthalmia.

As examples of the second class of cases, I shall also give, very briefly, three histories :

A girl, aged five years, while playing with a pair of scissors, stabbed herself in the right eye with one of the blades. The wound was well within the sclera, near the corneal margin. Dr. E. L. Holmes, who was first consulted, very properly advised excision of the globe, although for several weeks after the injury there was considerable vision in the eye. The friends of the patient refused to have the operation performed until it was too late. I saw the case more than a year after the accident, when the distracted parents were carrying the little girl from oculist to oculist, in the hope of getting relief. She had perception of light in the second eye, which, like the first, had been destroyed by a septic iridocyclitis. The injured eye had undergone atrophy and was perfectly sightless.

A year ago last February a Polish Jew, working in a machine-shop, was sent to me for an injury inflicted by a piece of steel that had entered the front of his eye at a point corresponding to the ciliary body, had passed behind the lens and vitreous, and had lodged in the posterior wall of the globe or had penetrated the ocular coats and escaped into the orbit, I am not in a position to say which. There was no marked disturbance of vision (V. = 2/7 and J. IV) when I saw the man a few days after the accident, but the eye was tender and injected, and there had been some intraocular bleeding. Here was a man who could ill afford to risk anything or even to remain from work for any great length of time. I accordingly explained to him, to his employers, and to his rabbi the dangerous character of the injury, but he steadfastly declined operation. He left me, and I heard afterward that he became blind in both eyes.

A young man, while chipping steel, in August, 1892, was hit in the right eye with a flying fragment. The missile penetrated the cornea, iris, and lens, and its ultimate destination could not be determined owing to the traumatic cataract that followed. I removed most of the latter by a corneal incision and cut through, with a DeWecker's scissors, the tough membrane that remained, and was finally able to inspect the back part of the eye. The vitreous was cloudy and I could barely see the fundus. However, with a glass the patient had V. of 1/5, and I determined to try to preserve the eye, although symptoms of sympathetic irritation (lacrymation, photophobia, and inability to read) were occasionally present. Under a general anesthetic the globe was pierced at its lower equatorial aspect with a Graefe knife and the point of a Hirschberg electro-magnet introduced through the wound into the vitreous. After some careful manipulation I was successful in fishing out an irregularly shaped piece of steel. The man made a good recovery; both eyes became comfortable, and vision improved, so that he was able to work with ease. Within a year, however, he began to complain of his old symptoms in the better eye, and although he had nothing that to my mind justified excision of the injured eye, he saw another oculist, who, I understand, removed it.

I am not prepared to say that this was not the wisest course to pursue, as workingmen cannot afford to give themselves the continued rest and care that should follow these electro-magnetic operations.

An example, and I shall give but one, of what I have termed the third class of ocular injuries, is the following :

A man, aged forty-five years, consulted me in June, 1891, for watering of his left eye, with general discomfort. He thought his reading-glasses needed changing. The eye complained of was somewhat injected, but not tender. Both distant and near vision were normal. The right eye was sightless, the tension was + 1, and the patient flinched when the globe was slightly pressed upon. There was some ciliary injection. The man said that lately the eye was occasionally tender and

sometimes got red like the other. Ten years before he had been hit in the left eye with a chip of steel that had penetrated the front of the eye, but had been extracted by a fellow-workman. After that he could not see out of it. There was a scar on the cornea, but nothing could be seen in the iris, except that it was of a dirty-brown color, while that of the sound eye was blue. There were posterior synechiæ and a whitish cataract. I enucleated the eye at once, and found a flattened piece of eroded and rusty steel 4 mm. long and 1 mm. wide, like the pointed extremity of a needle, imbedded in a brownish matrix of thickened vitreous, and lying close to the retina at the inferior aspect of the globe. The surrounding retina and vitreous were evidently stained with iron-rust. The man made a good recovery and has had no trouble since.

To return to the classification with which I started and in conclusion of this paper, I may say that my treatment of such cases may be summed up as follows: The eye is never to be enucleated or eviscerated in injuries of the first class; it is to be closely watched in all examples of the second class, and to be removed unless both eyes become and remain quiet. Lastly, injured eyes of the third class should always be removed.

As an aid to prognosis and treatment, I would suggest the following rules:

1. As long as the wound heals without difficulty, and no sympathetic irritation exists, I would treat with rest and antiseptics, and would not remove any eye whose injury is confined to the cornea, iris, and lens.

2. I would not enucleate an eye containing a foreign body when the injury was confined to these tissues and the foreign body could be removed.

3. I would not remove an eye containing a foreign body if there were no injury in the ciliary region, and the missile had passed through the posterior wall of the globe.

4. I would not immediately excise an eye injured by small shot (which are usually aseptic missiles), even if the wound were in the ciliary region, provided the patient could be occasionally seen by an oculist.

5. I would always excise an eye that contains a foreign body that could not be removed.

6. I would excise an eye in which the ciliary body had been injured, even if the sight were not much affected thereby. The only exceptions I would make to this rule are small gunshot-wounds, cases in which the second eye is useless or had been removed, and those instances in which there is no continued uveitis of the injured eye, provided always that the patient could be frequently seen by an oculist. For the average man, however, excision or exenteration would be, by far, the safest procedure in the last instance. When loss of sight goes along with ciliary involvement there can be no argument in favor of retaining the eye.

7. When once ophthalmia migratoria has set in, it is wise to retain the injured eye, if there be any sight in it, as eventually it may be the better of the two.

8. It is safe and proper to remove all continually tender or inflamed eyes of adults whose vision has been lost from a penetrating wound in whatever region of the globe.

9. It is highly desirable to retain the eyeball in patients under twenty years of age, if it can be done with safety to the better eye, as earlier removal of the globe retards the growth and development of the corresponding orbit, and greatly alters and mars the facial expression.

CLINICAL MEMORANDA.

SUDDEN DEATH FROM SHOCK DUE TO THE INTRA-UTERINE INJECTION OF A SOLUTION OF LEAD ACETATE TO INDUCE ABORTION.[1]

By PAUL J. BARCUS, M.D.,
of CRAWFORDSVILLE, IND.

On the afternoon of April 22, 1895, the dead body of Mrs. B. was found by a neighbor lying supine near a window on the floor of a bedroom in her residence. The dress was but slightly disarranged; the limbs were extended. Upon the floor, and quite near the body, were several vessels more or less filled. Among these was a teacup containing a powder and perhaps a half-ounce of liquid. There were lying near, also, a wire stilet and a bulb-syringe, with a linen catheter attached to it by means of a screw and thread. The contents of the cup were ascertained to be lead acetate, and there was some of the same solution in the syringe.

At the post-mortem examination, after making the usual median incision and grasping the fundus uteri, pressure would force from the vagina a fluid similar to that in the cup. None of the fluid could be found in the peritoneal cavity. On opening the uterus it was found to contain the product of a conception of about eight weeks' duration. The membranes were unruptured and the endometrium was not wounded.

The body presented the appearance of one having been in the enjoyment of perfect health. There was a history of good health—no heart-disease, no disease of any kind, so far as could be ascertained, to account for the sudden death. The woman had been talking to a neighbor at 11.36, and at 12.45 her dead body was found.

It was shown that the deceased had been in the habit of self-inducing abortions, and that she had successfully accomplished this no less than twelve or fifteen times. About five years ago a physician had attempted to produce an abortion for this woman by injecting pure tincture of iodin into the uterus. The injection was immediately followed by shock, from which the woman recovered, but which threatened for a time to terminate

[1] Read before the Indiana State Medical Society, June 10, 1895.

fatally. About two years ago she induced another abortion herself, which was attended by severe uterine colic and great depression.

Death must have been sudden and unattended with any marked convulsive movements, or some of the vessels near the body would have been overturned. The fatal result was due to the injection, as was shown by the history, and was attributable to shock, as there were no wounds made by the catheter, rendering it possible for air or fluid to have been injected into uterine sinuses.

A NEW METHOD FOR CORRECTING THE DEFORMITY OF PROMINENT AURICLES.

By WESLEY W. BARKWELL, M.D., AND JAMES BECKETT, M.D.,
OF CHICAGO.

CASES of deformity of prominent auricles are so infrequently met with and less frequently operated upon that it might be of general interest to relate a case and mode of operation. There have been three methods described for this operation: One by Ely, in which an oval piece is taken out of the entire thickness of the pinna, including skin and cartilage; another by Monk, consisting of the removal of the skin alone from the back part of the ear; and the last by Keen, in which a large oval piece is taken from the skin of the back of the auricle and a V-shaped groove taken from the cartilage, but not cutting through the skin on the inner side. In a case in which we operated upon April 29th the cartilage was very thick and firm, and this condition might have been the reason for suggesting a slight difference in the mode of procedure from any of those already mentioned. After preparing the patient in the usual way, by washing the ears and the surrounding parts with soap and water, an antiseptic solution, and then alcohol, we proceeded to outline an elliptic space on the back of the ears. This space measured in length about one-and-one-quarter inches, and in the center its greatest breadth three-eighths of an inch. It was our desire to take out this elliptic space without cutting through the skin on the front of the ears, and also that there should not be a redundancy of skin in this part. The knife was entered at one corner of the ellipse and the lower side cut out first, so that what little hemorrhage there might be would occasion no concern during the cutting of the other side. As the knife was drawn down toward the widest part of the elliptic space care was taken to slope the instrument gradually sideways more and more until it reached that point, and then gradually straighten it as it neared the other corner of the ellipse. This was done in order to take as narrow a piece as possible out of the front side of the cartilage, thus leaving no redundancy of skin on that side. After inserting the sutures and drawing them, the apposition of the parts was so complete, without any apparent redundancy, folds, or tension on the fore part of the ear, that from a front view it would be almost impossible to detect any evidence of an operation.

Dr. William C. Jarvis, Professor of Diseases of the Throat in the University of the City of New York, died at Willet's Point, L. I., on July 30th.

NEW DEVICE.

A NEW AND SIMPLE METHOD BY WHICH CAUTERY-IRONS MAY BE ELECTRICALLY HEATED ALMOST INSTANTANEOUSLY.[1]

By W. SCHEPPEGRELL, A.M., M.D.,
OF NEW ORLEANS, LA.:
ASSISTANT SURGEON EYE, EAR, NOSE, AND THROAT HOSPITAL; VICE-PRESIDENT NEW ORLEANS ELECTRIC SOCIETY, ETC.

WHILE at the World's Fair I was much interested by a new method of heating metals by electricity, the novelty consisting not only in the rapidity with which the metals were heated, but also in the peculiar method of applying electricity for this purpose. The metal, such as, for instance, a soldering-iron, was dipped into a bucket or jar containing a watery solution of borax and sodium carbonate, and in a few seconds became red-hot. A large, flat iron file, held in the solution, rapidly became white-hot, the heated metal standing out in brilliant contrast with the water; if the file was kept still longer in the solution it commenced to fuse rapidly.

A closer inspection showed that the bucket or jar was connected with the terminals of a 230-volt Edison current, the positive wire being attached to a plate of lead at the bottom of the jar, and the negative wire passing across the top of the jar. When used, the bar of metal was placed in contact with the negative wire, and the part to be heated was dipped into the solution, the heating process, as stated, taking place with remarkable rapidity.

It occurred to me that this method might be adapted to the heating of iron cauteries, which are still heated by the slow and cumbersome method of the charcoal-furnace or the blow-pipe oil-lamps. The heating of the ordinary platinum electro-cauteries leaves little to be desired, but this method is adapted only to the smaller cauteries, and cannot be used for the larger cautery-irons.

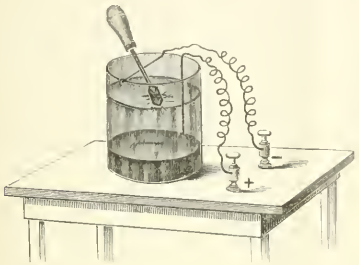
A series of experiments which I made with this method of heating cautery-irons has convinced me that it is not only simple and effective, but also quite economical. As a result of these experiments, I find that the average current required is 15 ampères at 230 volts, and the average time for heating the cauteries three seconds. The cost of each heating, as estimated for me by Mr. Coleman Reed, of the Louisiana Electric-Light Company, was about one-twelfth of a cent for one heating.

The apparatus is exceedingly simple. The vessel that I use is the jar of an ordinary bluestone battery, but any glass jar with a capacity of one or two quarts will answer the purpose. The jar is filled three-quarters with a solution of borax, 1 part; sodium carbonate, 10 parts; water, sufficient to make a density of 1.060.

A plate of lead, one inch wide, is coiled around the bottom of the jar, and to this is soldered the positive terminal. The negative wire is passed across the top of the jar, as shown in the accompanying illustration, and the apparatus is complete. The wires should connect with the Edison current-system of 230 volts, which is available in most cities in the United States and Europe. The ordinary cautery-irons may be used, the wooden or hard-rubber handles affording all the insulation that is

[1] Read before the Orleans Parish Medical Society, April, 1895.

required for the hand. It will be noted that I first place the neck of the cautery in contact with the upper (negative) wire, then as the point or knob of the cautery touches the solution it immediately becomes red-hot, and, if left longer in the solution, white-hot. To one who has never seen this method used before, the metal becoming heated on being immersed in a watery solution, and showing its brilliant incandescence through the water, the effect is very astonishing.



When we investigate the cause of the heating effect the theory that it is due to the resistance of the metal, as in the ordinary platinum electro-cauteries, will not explain the effect in this case. Fifteen ampères at 230 volts for three seconds would certainly not heat this large cautery perceptibly; and if it were a question of the resistance of the metal, it would become heated at the neck, where the resistance is greater, instead of at the large, rounded part.

The passage of the current through the iron no doubt has a slight heating effect, but the intense heat generated is due to another cause. When the electric current is passed through the solution electrolysis is set up, oxygen being liberated from the lead plate (positive terminal) and hydrogen from the immersed instrument, which is in contact with the negative terminal. This thin layer of hydrogen has a very high resistance, and at once becomes intensely hot and communicates its heat to the metallic instrument. The great heat of the hydrogen causes it to combine with the oxygen of the air, and this combustion adds to the heat of the cautery.

In experimenting with various metals for this process I find that the ordinary cautery-irons, as sold by instrument-makers, will answer every purpose. If made of copper, however, a somewhat longer time is required to heat them, but they will retain their heat for a longer period of time.

While the cautery-irons belong to the domain of general surgery, still I have found it serviceable to keep certain ones on hand. Quite recently I found this method of heating a cautery-iron useful in controlling an alarming hemorrhage after tonsillotomy, which the Paquelin thermo-cautery had failed to control.

As most hospitals and offices are supplied with the Edison current for illuminating purposes, this apparatus may be introduced with but little expense. The advantages of the method are its simplicity, reliability, and economy.

MEDICAL PROGRESS.

The Palliative Treatment of Jaundice due to Malignant Obstruction.—Russell (*Edinburgh Medical Journal*, July, 1895, p. 35) has reported a case of malignant disease of the pancreas in a woman eighty-five years old, with obstruction of the common bile-duct, occasioning intense jaundice, with profound symptoms of cholemia. A proposition to relieve the obstruction by operation was at first declined, and only consented to late in the disease when the conditions were most unfavorable. The patient lived only thirty hours after the operation, and post-mortem examination disclosed the existence of primary carcinoma of the head of the pancreas, without secondary involvement. The question is raised whether an operation for the relief of the misery and discomfort of a deepening cholemia is not so humane a procedure as tracheotomy for malignant laryngeal disease, as gastrostotomy for malignant esophageal stricture, or enterectomy or enterostomy for malignant intestinal obstruction. The advisability of operation would, of course, depend partly upon the possibility of making a diagnosis that could reasonably be regarded as accurate or complete. If the obstruction to the bile-duct were above the cystic duct, operative interference would be ineffectual, but with obstruction below that point draining the gall-bladder would remove the jaundice. Thus, a distended gall-bladder would indicate and warrant operation. If the gastric symptoms were not only prominent, but clearly attributable to gross involvement of the stomach, the removal of the jaundice would not give sufficient relief to warrant operation. If, on the other hand, the gastric symptoms appeared to be due rather to the jaundice than to a coarse lesion the relief of the jaundice would be followed by gastric relief. The presence of a duodenal lesion would not contraindicate operation. Even clear involvement of the liver would not necessarily be a contraindication so long as the distention of the gall-bladder showed that the hepatic duct was not blocked. The most perfect cases for operation would, of course, be those in which the lesion was confined to the head of the pancreas.

Extirpation of the Spleen for Echinococcus-cyst.—At a recent meeting of the Berlin Medical Society, Hahn (*Berliner klinische Wochenschrift*, 1895, No. 26, p. 576) reported the case of a woman, thirty-five years old, who presented a tumor as large as a child's head in the left hypochondrium, which had been noticed since the last labor, three months before. With the patient recumbent, the tumor extended upward to the left costal arch and downward into the hypogastric region, but not beyond the median line. Its surface was smooth, and its lower portion presented a sharp border, with an indentation. The tumor was but little sensitive and very freely movable. Distention of the bowel was followed by restriction of the limits of the mass. The patient had lost greatly in weight and strength, and desired to be relieved by operation. Heart, lungs, and kidneys presented no abnormality. A long incision extending an equal distance above and below the umbilicus disclosed a tumor in connection with the spleen, and provided with a pedicle of about the thickness of two fingers, constituted principally of vessels. The swelling conveyed a sense

of fluctuation. The capsule was thin, bluish-black in color, and in places presented yellowish-white spots of the size of a pea. It was concluded that the formation was either a hemorrhagic cyst, an echinococcus-cyst, or a cysto-sarcoma of the spleen, and after mature deliberation its removal, with the spleen, was decided upon. Accordingly, the pedicle was doubly ligated in six or eight sections with fine silk, and the spleen and new-formation removed, the pedicle replaced, and the abdominal wound closed. There was no complication; the temperature scarcely rose above the normal; bodily weight was at first lost, but later considerably increased. The proportion of colorless to red blood-corpuscles on the day of operation was 1 to 160; in the succeeding days, 1 to 300; then 1 to 400; and four months after the operation, 1 to 600. No swelling of the thyroid gland or of the lymph-glands was observed, and also no pains in the bones.

Dysphagia due to Abnormal Arrangement of the Great Vessels.—KELLOCK and BATTEN (*Lancet*, No. 3747, p. 1579) have reported the case of a healthy boy, two years and ten months old, who was severely choked while eating an apple, although nothing could be found in the larynx. The child was kept under observation for the night, but was dismissed quite well on the following morning. Nearly eight months later he was again hurriedly brought under observation with the history that he had suddenly choked while eating dinner. He was cyanosed and breathing with some difficulty. While awaiting treatment he became much worse and ceased to breathe altogether. The trachea was opened at once and artificial respiration performed for two-and-one-half hours, but without restoring breathing. Upon post-mortem examination a small blood-clot was found in the trachea, which had been opened by division of the fourth, fifth, and sixth rings. A large mass of granular-looking material (probably sausage) was found lying fairly loosely at the back of the pharynx, but it is uncertain whether or not it occluded the upper opening of the larynx. On dissecting the arteries arising from the aorta the following arrangement was found: There was no innominate artery; the two common carotids came off practically together, the left following the usual course, but the right crossing the trachea from the left side just above the sternal notch, to reach its usual position on the right side of the neck. The left subclavian came off from the arch of the aorta next, and followed a normal course; then came the right subclavian, arising from the descending part of the arch, and crossing obliquely behind the esophagus between this and the spine and behind the right scalenus anticus muscle to its usual situation at the root of the neck.

The Distinction of Syphilitic Neoplasms from Other New-growths.—At the recent meeting of the German Medical Congress, ESMARCH (*Wiener medizinische Blätter*, 1895, No. 26, p. 413) dwelt upon the peculiarities of syphilitic neoplasms, of which he had recently seen some forty. The cases belonging in this category usually present other manifestations of past or present syphilis, or give a history of that disease in parents or brothers or sisters. All tumors developing in the voluntary muscles should be viewed with suspicion. These occur most commonly in the muscles that flex and extend the head, in the abdominal muscles, in those of the back and of the legs, and also in the tongue. Especially suspicious are those growths that recur at regular intervals after extirpation, and which may be dispersed by the administration of potassium iodid in large doses. Likewise those growths should be viewed with doubt that disappear after the internal administration of arsenic, and also after attacks of erysipelas or the injection of the toxins of that disease. The mode of growth is not distinctive, some attaining considerable size rapidly, particularly after traumatism, while others grow slowly; neither is the consistency of the growth characteristic. Anatomically, syphilitic tumors present areas of fatty degeneration in the midst of grayish-red granulation-tissue. In case of suppuration the tumor should be removed surgically. Some syphilomata are not clearly distinguishable, even with the microscope, from round-cell or spindle-cell sarcomata.

THERAPEUTIC NOTES.

The Treatment of Human Tuberculosis with the Blood-serum of Goats Inoculated with Tuberculin.—At a recent meeting of the Société de Biologie, BOINET (*Compt. Rend. Hebdom. des Séances de la Soc. de Biologie*, 1895, No. 25, p. 543) related that he had found in a series of experiments that the blood-serum of goats previously inoculated with tuberculin had a controlling influence upon the development of human tuberculosis in guinea-pigs. Of a number of animals thus treated and subsequently inoculated with miliary tubercle the large majority resisted infection, a number of pregnant females even giving birth to healthy offspring. Upon the basis of these observations similar serum was next employed in the treatment of eight cases of tuberculosis in human beings. In three cases of slow progress, with dry cough or scanty expectoration, the results were favorable. In two cases in the second stage of the disease marked amelioration resulted. The treatment is thought to be of no avail in the advanced disease, associated with excavation, but rather in tuberculosis of slow course, with exacerbations, accompanied by fever, hemoptysis, night-sweats, and laryngeal complications.

The Treatment of Diphtheria with the Antitoxin.—At a recent meeting of the Berlin Society for Internal Medicine, EULENBURG (*Deutsche medicinische Wochenschrift*, 1895, No. 29, p. 472) made a preliminary report of the results of a collective investigation as to the results of the treatment of diphtheria with the antitoxin. Of 10,240 cases, 5790 were treated with the antitoxin, with a mortality of 9.5 per cent., while 4450 were treated without the antitoxin, with a mortality of 14.7 per cent.

RECENT SANITARY LEGISLATION IN PENNSYLVANIA.

ALTHOUGH sufficient time has not elapsed for the publication of the official volume comprising the acts passed by the Pennsylvania Legislature at its session just closed, we are advised through the Department of Agriculture of the approval of two acts having significant relations to the food-supply of the State. All attempts to secure an act controlling the milk-supply along the lines that have for a number of years been followed by the Board of Health of this city failed, partly from the organized resistance of the milk-dealers and partly from the unwillingness of the farmer-contingent to accept regulations that seem to be based upon purely theoretic views. By whatever motives of self-interest either of the opposing parties may have been influenced, it would probably have been more in the interest of the community at large if the Philadelphia officials had conceded something to the practical experience of the producers and purveyors of milk. The farmer-element is too strong in almost every State in this Union to permit the passage of laws that appear as even slightly opposed to its interests.

Some legislation, however, was secured concerning the milk-supply, namely, the passage of a brief act forbidding the addition of preservatives to milk. The terms of the act are comprehensive enough to exclude almost any article likely to be used for the purpose. It is generally known to sanitary chemists that the preservatives most commonly employed are boric acid and borax, with occasionally salicylic acid. There is much dispute as to the harmfulness of these ingredients, but as the law is specific in forbidding them, and as it is now pretty clearly established by numerous decisions of the United States Supreme Court that the right to declare a particular article injurious to the public health is reserved to the individual States in accordance with their laws, there is little doubt that the act can be used to prevent the use of these materials. That they are extensively employed, especially in the summer season, is well known. Many of them are sold as proprietary articles, without notice as to their composition, with more or less ingeniously worded certificates, from irresponsible chemists, as to harmlessness, and are used recklessly by the milk-dealers, of whom it may be said that while they are undoubtedly to blame for using anything that is foreign to the milk, they may in part be excused by the dependence which they are induced to place upon the indorsements furnished by the manufacturers of the preservatives.

In addition, however, to this specific act, a general food-law is now in operation, the enforcement of which is committed to the Department of Agriculture, and not, as might have been expected, to the State Board of Health. This somewhat unusual arrangement has arisen from the fact that two years ago the Legislature created the office of Dairy and Food Commissioner as an agent of the State Board of Agriculture for the enforcement of the oleomargarin-law. At the last session a Department of Agriculture was created, and the Dairy and Food Commissioner brought into that department. His powers were extended so as to include all the duties of supervising food-adulteration. The act is brief, and does not include specifically alcoholic beverages or drugs. In its phraseology it follows acts that have been passed elsewhere, and it is in slight conflict in one respect with the oleomargarin-act, inasmuch as the latter is absolutely prohibitory, and does not require the prosecuting officer to show a knowledge of the nature of the material sold, while in the recent act the prohibition applies generally to all kinds of food, and permits the sale of an article for what it is. Some interesting legal sparring may

be expected when prosecutions begin under this law.

All efforts in the direction of the prevention of food-adulteration must be regarded as merely experimental. Not only are laws passed with too little knowledge of the facts to secure a practical protection, but the interest of many manufacturing establishments, employing large capital, and capable of exerting pressure upon legislators, will be arrayed against many phases of restriction. Then it must be borne in mind that the newspaper press of the country is so completely subsidized by advertisers that no expression of public opinion contrary to the interests of such advertisers is to be expected. Acts, therefore, intended to secure publicity as to the composition of proprietary articles meet with the denunciation of all leading newspapers the moment the legislative situation becomes such as to suggest to the manufacturers of those remedies the necessity of opposition.

Legislation has also been enacted in Pennsylvania providing for the inspection of cattle, mainly suggested by the dangers of tuberculosis. We shall probably derive more substantial benefit from this source than from the food-laws noted.

THE STATUS OF SURGICAL TREATMENT IN PUERPERAL SEPTICEMIA.

THE treatment of puerperal septicemia has hitherto been palliative and expectant, both on account of the difficulty in localizing the infective process in given cases and from the elusive character of the symptoms. Although there are instances in which surgical treatment is demanded, we still have to deal with cases that are entirely beyond the reach of surgery. In the first class either the point of origin of the infection or the area made continuous with it by means of the lymphatic circulation remains the seat of the developed process; in the second class the toxemic element influences the aspect of the disease.

There are two sources of error to be guarded against in the management of cases of puerperal septicemia amenable to surgical treatment: First, the difficulty in determining the seat of infection—whether it be extra-peritoneal or intra-peritoneal, the chance of drainage outward in the first instance and the necessity of either partial or total extirpation of the pelvic organs in the second depending upon the accuracy with which we differentiate the seat of infection; second, the choice of time for operation—whether in the early absorptive period of the disease or in the developed stage.

Pathologically, the form of infection in these cases depends upon the character of the infecting elements and upon the degree of local resistance. If we were able to establish the relation between the symptoms and the pathologic process in each case we should be enabled to differentiate between those cases amenable to surgical treatment and those beyond its aid. In this, however, the difficulty in treatment lies.

The disease in its development assumes one of three forms, considered anatomically: First, a local infection, the result of necrotic endometritis extending by lymphatic involvement to the pelvic connective tissue. Second, a localized suppurative process terminating in either a phlegmon of the broad ligament or an ovarian abscess. Third, a general infection, expressed locally by a diffuse peritonitis, the result of active absorption by means of the lymphatics of infective material from the original seat of infection, and generally by the symptoms dependent upon pyemia.

Surgery is applicable probably only to the second division of cases, and if we exclude curettage from the radical surgical procedures the field is extremely limited. Total extirpation of the uterus is recommended in puerperal parametritis with suppurative lymphangitis of the uterine tissue, and the class of cases in which this association appears might be included in the first division. In the last division of cases surgical treatment is inevitably fruitless.

Practically, the landmarks by which we are to choose our way are misleading. This is best illustrated by the character of the symptoms in acute septic toxemia (sapremia). In this form of the disease the physical signs, as well as the symptoms, may, on the one hand, point to a parametritis with uterine involvement, or on the other to a localized suppurative process, whereas the local process may be entirely subordinate to the general expression of the disease, so indistinctly do the diagnostic points present themselves. Every practical obstetrician must have encountered cases in which the signs of a local infectious process have been present, namely, local infiltration, intestinal paralysis, and fetid lochia, perhaps together with the pain of peritonitis and the irregular temperature of suppuration, and yet post mortem not a single local indication is to be found that would have warranted surgical interference.

In view of these facts it seems fitting to enter a plea for the closer study of diagnosis in connection with puerperal septicemia. Skill in diagnosis will depend largely upon two factors—always excluding the essential ability for painstaking observation, characteristic of the scientifically qualified practitioner—first, upon the amount of practical experience to be counted among the resources of the diagnostician, and, secondly, the degree of general and special training he has received in the observation of symptoms.

As a rule, the men who are best able to operate are those who unfortunately are least able to separate mentally the operative from the non-operative cases, because they have usually met with only the former.

May not our reliance, therefore, upon surgery yield in some degree to an appreciation of the art of diagnosis, whether diagnostic acumen be the criterion of either obstetric or surgical skill?

EDITORIAL COMMENTS.

Trinity Church Tenements.—In a report before us, just issued by the Corporation of Trinity Church, New York, an effort is made to refute the charges laid before the Tenement-house Reform Commission last December, reflecting seriously on the management of the property held by that church.

Mr. Frederick L. Hoffman, statistician, was engaged to study the death-rate and the causes of mortality among the population of the Trinity tenements, and his article forms the principal part of this report.

Several previously published letters are appended, and one written by the rector of the church contains these words: "As to model tenement-houses the corporation is not without experience. It has already erected ten such houses, not one of which has incurred the criticism of the committee; but not one of them is full, and, if filled, they would not net more than 4 or 5 per cent., and in fact have not netted more than 3 per cent." A few lines further on it is said that "the trustees do not feel that it is their duty to engage in enterprises which do not commend themselves to *business judgment.*" Here the whole matter rests. The world demands that a religious body, whose object is the furtherance of morality, shall conduct whatever it undertakes on ethical principles, no matter what the pecuniary consequences are, and when it ceases to do this it must submit to censure. A friend of Trinity in another letter published in the report reiterates the fact that Trinity conducts its *business* as *other business* is conducted, and that it is "a harsh judgment which insists that the work of removing old and (unsanitary) rookeries and constructing new buildings shall proceed faster than the interests of the corporation demand."

Which interests we ask? The business interests would never demand their removal, as the best-paying property is that which is the most unsanitary, namely, the hovels of the slums.

Mr. Hoffman's work shows a careful study of the records, but is open to several criticisms, which, if just, would invalidate his arguments that Trinity tenements are healthier than other houses in the same locality.

We agree with Mr. Hoffman that it is wrong to compare the death-rate of a group of individuals situated in one part of the city with the death-rate of the entire population; and also that it is not always fair to compare the health of one-thousand individuals with that of one-million, though living under similar conditions; but we would add that it is not proper to compare one set of tenements with another set, though situated on the same street, without analyzing the elements in the population of each. Thus, if negroes inhabit one row of houses and Jews another, other things being equal, the sanitary condition of the two tenements may be equally good, yet the death-rate would be much smaller among the Jews than even the general death-rate, while among the colored it would be much greater.

Another fact that Mr. Hoffman has ignored is the proportion of children living in Trinity tenements as compared with the proportion in other portions of the district. The greater the number of children under five years of age, in a given population, the greater the death-rate will be.

The methods made use of by Mr. Hoffman to prove that Trinity tenements are more sanitary than other houses in the same locality, namely Ward 8, District A, are as follows: First, he compares the death-rate of Trinity population for the year 1891 with that of the district for the same year, and finds a difference in favor of Trinity; but, as Mr. Hoffman states, the time-element is too limited, and so he makes use of other methods. Forty-one "selected tenements" are compared with eighty-three Trinity tenements for a period of two years, and again Trinity makes a favorable showing, although the specially selected tenements are not in the same locality. The third method used is the comparison between the mortality in Trinity tenements and the mortality of the district for a period of six years, although the periods are different, that for the tenements being from 1889 to 1894, and that for the district from 1885 to to 1890. When a small population is concerned some slight epidemic in one year might materially alter the mortality-rate.

In a table compiled by Mr. Hoffman, showing the causes of death in the tenements for the period 1889–94, the zymotic diseases are shown to be less prevalent than in the wards of the city at large, and from this he concludes that the charges of the Board of Health that the unsanitary condition of the Trinity tenements is the cause of an excessive death-rate cannot be substantiated.

That the property in question "is not so bad as it was painted" is probably proved by this private investigation, but it would have been more convincing if the analyses were more complete, and if a commission of disinterested persons had been invited to make the investigation.

The corporation has still to meet the charge that its tenements are not all that they should be. They may not be as unsanitary as they were reported to be, but *are they as healthy and as free from fault as they might be?*

Is Trinity corporation like so many individual philanthropists and churchmen, who preach morality on Sun-

day and endow hospitals and schools, while in their business relations they are as grasping and unbrotherly as they possibly can be, and, when they are taken to task for their hypocrisy, respond that business principles are one thing and brotherly love principles something entirely different? Their employés are bought in the cheapest market and taken advantage of whenever possible. Property must yield 5 per cent. per annum, no matter who suffers.

The issuing of this report on the sanitary condition of Trinity Church tenements does not in the least satisfy the demands of public opinion, namely, that a professedly religious body should endeavor to conduct its business affairs on the same ethical basis as its spiritual affairs are conducted, and if it does not do so, then it deserves public censure.

Orthographic Ignorance and Medical Ability.—There can be no question that men have shown ability to do good intellectual and social work of undoubted value to civilization who could not spell ten words correctly. It is said that there is in the United States Senate to-day a millionaire who was formerly the Mayor of his native village, and that in the town-records his signature to hundreds of documents exists with the official title "mare" (for *Mayor*), appended by himself. It needs only to be added that he was a good Mayor, and had at least good *horse*-sense, and is to-day a better legislator than most of his associates. Just as frankly may it be admitted that many a physician of the present, as of past generations, is unable to master the difficulties of English orthography.

But, and here's the rub, that day is either past or should be past. It is by everyone admitted, and by none more fully than by the combined good physician and poor speller, that without the preliminary education, evidenced at least by correct spelling of one's native language, the modern physician is now and henceforth not only handicapped, but utterly outclassed in the race of life. It is not that knowledge of spelling will make one the better physician, but the lack of that knowledge certainly guarantees other lacks that squarely debar from the higher education essential at this day. It has been said that without money, or a certain amount of it, one cannot get what money alone cannot buy, and it is much the same with preliminary education. In the orthographic ignorance of the recent graduate there is, moreover, a bit of hypocrisy to be exposed. Somebody is "uttering false paper," as the lawyers would say, or false sheepskins—or, in plain English, some one is lying. All of our medical colleges are pretending that their preliminary examinations are real and not tricky shams and frauds. What is the fact? Have genuine preliminary examinations been held in the cases of men who spell after the manner of those cited herewith? Nay, in their "final exams.," preparatory to graduating them, what was the condition of mind of their professorial examiners?

The following list of words is culled with exact spelling from the papers of those examined by the "Board of Medical Examiners, representing the State Medical Society of Pennsylvania," at its last examination. "Some of these gentlemen," writes the examiner, who kindly sends us the list, "were graduated this year by medical colleges in Philadelphia:"

Athromatous.	Murmer.

Nostrum-advertising in Medical Journals.—The Medical Society of the State of Pennsylvania has sent out the following circular, to which we heartily subscribe:

To Editors and Publishers of Medical Journals:

As a committee appointed for that purpose we desire respectfully to call your attention to the following extracts from minutes showing the action taken by the Trustees of the American Medical Association and by

the Medical Society of the State of Pennsylvania, respectively:

"Baltimore, Md., May, 1895.

"*Report of the Trustees of the American Medical Association.*

"During the year no advertisements of secret remedies have been accepted that were not accompanied by a formula, but to comply still further with what appears to be the desire of a large number of those interested in the highest success of the *Journal* the editor, with the termination of the present contracts, has been instructed *to accept no advertisements of medicinal preparations the proprietors of which do not give a formula containing the official or chemic name and quantity of each composing ingredient to be inserted as a part of the advertisement.*"

"Chambersburg, Pa., May, 1895.

"*Resolved*, That the Medical Society of the State of Pennsylvania congratulates the American Medical Association upon the decision of the Trustees to exclude unethical advertisements from the *Journal* of the Association."

"*Resolved*, That a committee of three be appointed to communicate with the editors and publishers of medical journals in the United States, calling their attention to this action of the American Medical Association, and requesting them to accede to the wishes of the profession by adopting a similar rule."

Allow us also fraternally to state: That we believe that the best interests of medical men are coincident with scientific accuracy, so far as this can be obtained: That the practitioner of medicine should therefore know in all cases the character of the drug, and the formula of the preparation or chemic compound that he prescribes: That the use of a secret preparation, or nostrum, is undeniably unscientific, and cannot be intelligently defended: That hence the advertisement of such preparations by scientific journals is out of place; its effect being to promote quackery and discourage scientific prescribing: That we believe the exclusion of such advertisements will aid the circulation of medical journals, and give them a dignity and character not obtainable without such exclusion: That the hearty manner in which the action of the Trustees of the American Medical Association and that of the Medical Society of the State of Pennsylvania was received shows the very cordial indorsement by the profession of the policy here recommended. We, therefore, most earnestly, ask your careful attention to this subject, hoping and in behalf of this society requesting that you will adopt a similar rule to that of the Trustees of the American Medical Association.

Very respectfully yours,

S. S. Towler, M.D.,
Marienville, Pa.;
J. J. Buchanan, M.D.,
1924 Penn Ave., Pittsburg, Pa;
C. H. Thomas, M.D.,
1807 Chestnut St., Philadelphia, Pa.
Special Committee.

Artificial Caffein.—Another triumph for the laboratory has just been recorded in the synthetic manufacture of caffein. This is an important advance not only in itself, but also in its suggestion of future progress. The process requires as yet such an elaborate series of chemic operations as to make the cost of the product considerably above that of natural caffein. But only a mere simplification of the process is required to remedy this, and that is sure to come with perseverance and practice. This field has been a most tempting but barren one to the chemist for generations past. For a long time it seemed absolutely hopeless to attempt to rival protoplasm in its transforming and constructive powers. When at last the synthesis of urea was achieved, some fifteen years ago, it was hailed as a great triumph. Slowly but painfully one product after another has been achieved, but so far these have been mainly the results of excretory metabolism. A few months ago, however, the formation from inorganic materials of something seemingly identical with albumin was announced, and now such a complex and active body as caffein has been reached. It looks as if not merely a new field, but a new world of possibilities were opening up to us. No less an authority than M. Bertillon is most sanguine about the prospect, and declares that it is only a question of time—and a short time at that—when we shall be able to construct all of our food-materials directly out of the elements without the assistance of either plant or animal. At present, however, it is much simpler to throw a few seeds into the soil and let them work the miracle for us, and we seriously doubt whether, even if by straining to the utmost, we can imitate Nature's results, we can ever hope to attain to the ease, simplicity, and beauty of her processes. Bertillon's prediction, however, is certainly among the possibilities—and how it would delight our vegetarian and our "peace-principles" friends! There would then be no more excuse for slaughter of any sort, no more animal foods to heat our blood and excite us to deeds of violence. Plants may be grown for their beauty and animals for the pleasure of their companionship, and meat-eating will become as unnecessary as cannibalism has almost become. What a real millennium it would be! Not only could the lion lie down with the lamb, but the butcher with the kid. In that Utopia would the ghost of Malthus rise up to warn—or perhaps to enjoy?

S. Weir Mitchell, M.D., LL.D.—The American medical profession must feel a deep sense of pride in the honor conferred upon one of its most distinguished members by the University of Edinburgh in granting its honorary degree of Doctor of Laws to Dr. S. Weir Mitchell, as "the chief ornament to medical science in the New World." Dr. Mitchell is well known not only as an able neurologist, but as a practical physiologist, and a strong all-around medical man, not to speak of his lyric and general literary abilities. Himself a prodigious and tireless worker, with a most fruitful and suggestive mind, the force of his example and the aid of his counsel have had a most potent influence for good upon those who have been fortunate enough to be thrown into professional relations with him; and he has created a school of younger men who promise to carry on the good work in scientific medicine that he has begun. Dr. Mitchell is already rich in the possession of the Doctor of Laws degree of our own Harvard and of an honorary degree of Doctor of Medicine from the University of Bologna.

REVIEWS.

THE EYE IN ITS RELATION TO HEALTH. By CHALMER PRENTICE, M.D. Pp. 214. Chicago: A. C. McClurg & Co., 1895. Price, $1.50.

OPHTHALMOLOGY nowadays seems literally to teem with new truths, as a dog is said to teem with fleas. The present remarkable book has added to the number immensely. In the short space of 200 pages we have a cock-sure theory of inflammation, of hypnotism, of eye-strain, of drunk-cure, of all disease in fact. Like Pico of Miradola, the author treats *de omni re scibili et quibusdam aliis*, especially the *quibusdam aliis*. Pathologists will be interested in the certain settlement of all the problems that torment them, and Keeley must now look to his laurels and his dollars. Ophthalmologists will be pleased to learn how diabetes and all other evils of human flesh can be cured by "fogging" and "repression" and tenotomies of eyes without a trace of ametropia or of muscle-imbalance. The origin of myopia and of astigmatism, and their cure, are real gems of ophthalmic wisdom. The learned author has studied the eyes of the dead with much diligence; why did he not raise the dead with some of his new truths? Perhaps he has done so, but with praiseworthy conservatism is waiting until a greater length of time and a greater number of cases shall warrant reporting. To the specialist and his journal must be left extended criticism of this unique work. It will be "nuts" to them. The author has got hold of the tail-end, as it were, of some genuine truths, but the chief use of the volume, we suspect, if it have any influence besides a mirth-provoking one, will be to make "American ophthalmology," that sweet morsel in the cheek of European ultra-conservatism, still more the butt of just and unjust ridicule. It will perhaps also entrench the native skeptic in a dogmatic reactionism as pernicious and as extreme, as regards genuine ophthalmologic progress, as this poor sinner is guilty of in his furious whimsicality. As to his two great great discoveries, "Fogging" and "Repression," he is certainly an adept in the first, and it only remains for the profession to put the latter truth in energetic practice. We catch a glimpse of the true etiology of the author's discoveries in his praise of "orificial surgery" and *similia similibus*. Lest it be thought we are too severe we quote a few illustrative passages:

"In glaucoma one of the most popular treatments is iridectomy, also division of the ciliary muscle, called cyclotomy."

"Disease (as ovaritis) is localized abnormal innervation, and always central in the nervous system, being a lack or excess of motive-force. The growth of tumors is due to abnormal innervation. A lesion is always a result (of disease) not a cause."

"So-called cures of dipsomania perform whatever good they effect by temporarily relieving eye-strain" (by the mydriatic in the "jab").

"Look into the dim windows of the brain twenty-four hours after death and a deviation of the eyes from a perfect position will always be found."

"A large percentage of consumption takes its origin from irritation through the visual centers."

"Latent hyperopia where mydriatics fail."

"Nervous ailments are not so common in foggy climates, because the sight-centers are not exercised so much as in a clear, bright view."

DEFECTIVE SPEECH AND DEAFNESS. By LILLIE EGINTON WARREN. New York: E. S. Werner, 1895.

IN this little book Miss Warren shows that "fluent speech may be obtained and understood by all who suffer from the different phases of deafness and the different degrees of imperfect utterance." The little book contains, furthermore, many valuable hints for the physical, ethical, and moral training of any child, whether deaf or not. In Chapter I it is maintained that the "first positive proof of hearing is in the young child's outcry of pleasure when affected by music or other sound;" in Chapter II, that "through the sense of hearing the affections are reached;" and in Chapter III, that talking aids thinking and further intellectual development. In Chapter IV is advanced the idea that "in the healthful exercise of the lungs (in speech) lies the prevention of pulmonary diseases to which the deaf mute is peculiarly subject." In Chapter V "the child suddenly deaf and the child growing deaf slowly" are considered. It is shown in this chapter that the most unjust treatment for a partially deaf or partially mute child is to remove it from school-association with children who hear and speak well. Deprived of such influences the defective child grows worse. "A child possessing but a small amount of aural power, who has once had a good perception of sound, could maintain his place in any ordinary school, if, from the first manifestation of his deafness, he were taught to use his eyes in the place of his ears."

In Chapter VI the very important fact that "the deaf child does not know what sound is," and the vital necessity, as well as the possibility, of "teaching the deaf to hear" with the hearing most of them still retain to at least a slight degree, are presented. In Chapter VII it is shown that the "hard-of-hearing adult," having, through hereditary influences, acquired language by the ear, may by educative means continue to enjoy conversation by the eye.

In Chapter VIII dull pupils, usually those "merely suffering from a defect in hearing," in Chapter IX "invented" or "pathological language," and Chapter X "lisping and careless speech in general," are considered. In the latter chapter "the sentence-method of teaching pupils to read," says the author, "I fear will only increase the slovenly speech of American children." . . . "I would urge that teaching to read be an exercise founded on knowledge of the mechanism of speech." Chapters XI and XII treat respectively of "stuttering and stammering" and "cleft palates."

OBSTETRIC SURGERY. By EGBERT H. GRANDIN, M.D., Obstetric Surgeon to the New York Maternity Hospital, Gynecologist to the French Hospital, etc.; and GEORGE W. JARMAN, M.D., Obstetric Surgeon to the New York Maternity Hospital, Gynecologist to the Cancer Hospital, etc. Royal octavo, 220 pages. Philadelphia: The F. A. Davis Co., 1895.

DRS. GRANDIN and JARMAN have written a thoroughly practical work upon a teaching-basis, and, therefore, necessarily one of paramount interest. There is much in it worthy of special note—far more than we have space to give to it—and a few points only that we cannot indorse. Fifteen photographic plates, showing the

stages of the various obstetric operations as performed upon the manikin, are distributed throughout the book, and with the eighty-five illustrations in the text contribute materially to the teaching-value of the book. It is to be regretted, however, that the drawings could not have been largely taken from Nature. The advantages to be derived from thorough asepsis and antisepsis are ably set forth, and some valuable suggestions as to the perfection of the antiseptic management of labor are offered. Notably may we mention in this respect the preference shown for creolin as an obstetric antiseptic agent. Creolin, with the possible exception of lysol, is the safest and most efficient pharmacopeial agent in obstetric surgery, not only as a germicide, but also as a lubricant, and as such we can strongly indorse the position taken in the remark that "the vaselin-pot"—and we might add the lard-pot—"should once and for all be banished from the lying-in chamber." The section on pelvic deformities could very easily have been more thoroughly elaborated, but the various obstetric operations are generally presented in a concise and practical manner. A certain degree of inaccuracy may be noted, especially in grammatic construction and in orthography. Thus, we are acquainted with Baudelocque's valuable work in obstetrics, but his name appears strangely unfamiliar when spelled Beaudelocque, and sentences such as the following, on page 12, are, to say the least, not euphonic: "It cannot be emphasized too strongly that the physician is to-day not guiltless who, whenever it may be, does not practice pelvimetry." Hypercriticism is never justifiable, but such defects as the foregoing mar perceptibly a truly valuable work. As it stands, the book must be recommended as a serviceable one for the student of obstetrics.

Atlas des Gesunden und Kranken Nervensystems Nebst Grundriss der Anatomie, Pathologie, und Therapie Desselben. Von Dr. Christfried Jakob. Mit Einem Vorwort von Prof. Dr. Ad. v. Strümpell. Munich: J. F. Lehmann, 1895. 10 marks ($2.50).

This atlas of normal and morbid conditions of the nervous system, which is the ninth volume of the series, is largely the result of observations made at Strümpell's clinic at Erlangen, and contains seventy-eight plates, mostly colored, and fourteen woodcuts, with descriptive text. The illustrations cover serially the general morphology of the nervous system, its development and structure, its topographic anatomy, and its general and special pathology. The text proper, to which 194 pages are devoted, discusses, in addition to the subjects illustrated, the anatomy and physiology of the more important nerve-paths, the general and special therapeutics of diseases of the nervous system, and, briefly, a number of diseases of unknown origin or localization, including exophthalmic goiter, myxedema, akromegaly, tetany, and tetanus. The concluding section comprises suggestions as to the best methods of preserving, preparing, and studying nervous tissue. Altogether the work appears to be well and faithfully done, and should prove a useful aid to the student of diseases of the nervous system.

Skiascopy and its Practical Application to the Study of Refraction. By Edward Jackson, A.M., M.D., Professor of Diseases of the Eye in the Philadelphia Polyclinic, etc. With 26 illustrations. Philadelphia: The Edwards and Docker Co., 1895.

All ophthalmologists will welcome Dr. Jackson's little manual. It is an authoritative and excellent exposition of the subject with which it deals. We agree essentially with the author in his estimate of the value of this method, in the hands of those who have mastered it—a mastery, however, not easily obtained. The refraction ophthalmoscope and ophthalmometer do truly "give very inferior information." Of course, the only reliable test for the refraction of intelligent adults and young people is the subjective test with the test-types and test-lenses. But for children, for some amblyopic eyes, and for the stupid, skiascopy is the most trustworthy objective method and has the field. Another use for it that may be found is in hospital and even in private practice, in the hands of those who have not the desire or the time to do the most accurate work by the subjective method—a method that requires patience, time, and care.

Early Scoliosis, or Curable Curvatures of the Spine. By Percy G. Lewis, M.D., M.R.C.S., etc. Illustrated. Pp. 50. London: John Bale & Son, 1895.

English monographs are often disappointing to Americans on account of their small size, but, as they contain much practical information in a short space, one has but to read them carefully over and over to increase their value indefinitely.

This little work before us contains much of real value upon the treatment of curable scoliosis, and this includes the majority of cases treated early and persistently.

The importance attached to hygiene, especially fresh air; exercise short of fatigue; improved habitual positions; the discarding of supporting apparatus; the development of groups of weakened muscles; to be followed by a course of general gymnastics, are all to be heartily commended and indorsed. The relations of the surgeon to the gymnastic-master are well pointed out, but the importance of massage and Swedish movements appears to have been neglected.

The Middlesex Hospital. Reports of the Medical, Surgical, and Pathological Registrars for the Year 1892. London: H. K. Lewis, 1894. Price, 2/6 net.

The medical and surgical reports comprise, each, a summary of diseases and abstracts of cases; and as an appendix there follows a "Summary of Gynecological Cases." The extensive post-mortem tables of the pathologic report contain the record of 296 cases, of which 172 were medical and 124 surgical.

Among the interesting abstracts of exceptional cases in the medical report is one of myxedema in a woman, who was "placed under the 'thyroid' treatment" and recovered.

Dr. Samuel S. Adams, of Washington, D. C., who has been Professor of Clinical Pediatrics in Columbian University, has been elected to the Chair of Diseases of Children in the University of Georgetown.

CORRESPONDENCE.

SO-CALLED OTO-MASSAGE.

To the Editor of THE MEDICAL NEWS,

SIR: Much has appeared within the past year in the medical periodicals, especially in the United States, upon so-called oto-massage, or passive motion in some form, applied to the ear for the improvement of hearing.

The procedures described and advocated by the writers of these articles may be divided into two classes: first, methods of systematic acoustic exercise of the *sense* of hearing by repeating vowels and isolated words near the deaf ear—the method of Urbantschitsch, of Vienna; and, second, procedures consisting in the application of direct force by pressure-sounds, probes, etc., to the membrana tympani and the malleus, and the conduction of musical notes and simple vibratory motions by various apparatus directly into the auditory canal—so-called pneumo-massage and phono-massage.

The first class of procedures, the only ones with an otologic status, are not new with Urbantschitsch, as he admits (*Wiener medizinische Presse*, October 21, 1894), having been already described and tried by Itard, Toynbee, and Benedikt long before. The improvement in hearing that Urbantschitsch has obtained in the very deaf is marked in some cases; but relapses, he states, ensue in all of them. The improvement he has effected by his acoustic exercises he regards as an intellectual rather than a sensorial one, as does also Benedikt (*Berliner klinische Wochenschrift*, July 30, 1894).

So far as concerns the second class, all forms of masseurs, it may be said they have absolutely no scientific otologic standing, and were pronounced useless, and even harmful, in a discussion on the subject at the meeting of the American Otological Society, May, 1894.

All forms of *direct pressure* on the membrana tympani must manifestly bruise and wound this structure, while the direct conduction of sound from vibrating instruments, etc., into the external auditory canal fatigues the ear very easily, as some of its promoters admit, and must necessarily have the same kind of effect upon any ear weakened by chronic catarrh as the noise of the telephone has, or as that of pounding rivets into place has on the catarrhal ear of boilermakers. It is plain, therefore, that all procedures of the second class must do harm to the patients, and their exploitation, as of late in some American medical journals, savors of methods I hesitate to name.

Truly yours,

C. H. BURNETT.

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.[1]

Sixty third Annual Meeting, held at London, July 30 and 31, August 1 and 2, 1895.

FIRST DAY—JULY 30TH.

SIR J. RUSSELL REYNOLDS, delivered

THE PRESIDENT'S ADDRESS.

After referring to the last meeting of the British Medical Association in London, in 1873, presided over by the late Sir William Fergusson, and when the address in medicine was delivered by the late Edmund Alexander Parkes, he referred to the vast strides that had been made in the elucidation of both structure and function—such, for example, as in the researches upon the thyroid, the adrenal bodies, the spleen, and the liver; the advance of bacteriology; the functions of the axis-cylinder of nerves; and the magnificent prospect of a new field of therapeutics in the serum-treatment of disease.

Attention was called to that which may be considered the most striking fact of modern physiologic, pathologic, and therapeutic research, namely, the power of "living," things for both good and evil—namely, in the conservation of health and in the prevention or cure of disease. The mineral and inorganic world has helped much, but now help and hope come mainly from organized products and still living agencies.

The delicate phenomena and suggestions of "living" and "chemic" functions are under minute survey, analysis, and detail—the points where they touch, the mode in which facts of either may be rendered in terms of the other; their bearings upon the life of animals and men, both as individuals and as parts of a community: the diagnosis of the most obscure diseases, and the tentative and more than tentative endeavors to counteract poisons, which can be separated but not destroyed, over-ruled but not abolished.

In the schools there has been great improvement in the mode and scope of teaching; and this especially in its being less didactic and more practical. Much of the old-fashioned, often dreary, "lecture" of an hour's duration has passed away, and in its place is a "demonstration," an "object-lesson," a conversation, or examination. These are more useful and therefore more attractive to the students; and, at the same time, more trying, but none the less efficiently rendered by the teachers.

Again, in clinical teaching there are much more and closer personal relationships, not only between physician and student, but between student and patient. The latter is not a mere "dummy" in a bed, exhibited as a specimen of this disease or that, but a "human being" to be spoken to and to help the student to find out whether or not the card at the head of his bed, on which the diagnosis of his malady is supposed to written, is correct, or as full as it might be.

Then there is another point particularly noticeable when demonstrations are being given, either at the bedside or in the laboratory, namely, the far greater interest and earnestness that characterize the student of to-day as compared with his predecessor. Much of this is due to the indulgence of a larger hope. Hidden as still are the great mysteries of life, there are yet definite facts to be grasped by the mind, to be seen and handled, not only imagined or asserted; and the place of these facts in the economy of Nature, their bearing upon others, and their relation to work yet to follow, give a precision and confidence to study that is, comparatively speaking, of modern growth. There was plenty of assertion and show of knowledge in the past; but even the teachers did not believe the half of what they taught, nor comprehend the half of their sage pronouncings. Nature has, as it were, taken man more into her confidence, and daily reveals so much, even while concealing more, that the learner stands firmly on the ground he has gained,

[1] From advance-sheets kindly furnished by the British Medical Journal.

instead of trembling on a quagmire, the length, and breadth, and depth of which he could not see and did not care much to imagine or investigate. He felt sure of little then but of his own and his teacher's ignorance, but now he grasps much that is ascertained truth, and such as can be seen, shown, measured, and recorded with perfect accuracy.

There are some points in the present state of scientific precision in which it would appear that but little advance has been made. Much more is known about diseases, their origin, their anatomy, pathology, interrelations, modes of ending, and their treatment; but with regard to nosology and nomenclature there is little of which to be proud. Groups of symptoms have been described by different observers as marking some tolerably distinct departures from recognized types of malady, and, for want of any nosologic position being assigned to them, they are called after their first describers' names, and so we have not only Bright's disease, Addison's, and Graves', but a host of others, often indeterminate in character, going by the name of Friedreich, Raynaud, Hodgkin, and others, until there is a fair prospect of every distinguished pathologist or clinical investigator being handed down to posterity as a disease, the name of which conveys no semblance of a meaning as to its nature. Still further, and more to be deplored, there are smaller groups of symptoms that are not honored by receiving the names of their describers as separate diseases, but the names of the observers are tied on to the symptoms; and so Cheyne-Stokes' breathing, Corrigan's pulse, von Graefe's sign, somebody's else phenomenon, and a multitude of other like phrases are used, to the great confusion of the student, and not only so, but to his real and permanent injury. For what is easier to say than that there is "Cheyne-Stokes' breathing," except to feel a sense of rest in having made use of that learned phrase, and so practically to shut the door to further inquiry as to what it means and how it comes about, what its diagnostic or prognostic value may be, and how it bears on therapeutics?

Of course, to give the proper name to a disease is to place it where it should be, nosologically, "at home," and understood; but medicine is not a science yet sufficiently "ordinated" for this thing to be done, and so we grope about, and "gather dust and chaff," with little chance or hope of turning them to value; and instead of making this the matter of most serious investigation, and finding the true relation between the new "group of symptoms" and those others which form the central facts, the backbone and whole skeleton of pathology, we lay hold of the first piece of red tape ready to our hand, tie up the group of symptoms in a bundle, and label it Brown's, Jones', or Robinson's disease!

At the very time that there is this increasing use of loose phraseology, there is also—as is common enough in other departments of life—a marked tendency in the opposite direction, and that is to connote as diseases certain groups of symptoms by some short, or long, and often not very appropriate word or words, such as akromegaly, hypertrophic pulmonary osteo-arthropathy, appendicitis, pseudo-hypertrophic muscular paralysis, and others. There is abundant precedent for this; some are time-honored and old enough to be allowed to live, such as pertussis, epilepsy, apoplexy, chorea, gout, and rheumatism, which have the merits of brevity and of meaning; but there have crept into ordinary conversation nowadays a number of expressions which aid us little, or not at all; and such words as gastro-jejunostomy and laparotomy do little more than lay us open to the satires of the playwrights of the last century in foreign countries, and its predecessors in our own.

But whatever may be our failures—and they are small compared with our enormous successes—there is nothing that has happened during the past twenty years to be compared in importance with the new revelations that have been made of the potency and pre-potency of life—the power of life in life—in health, in disease, and in its treatment. These include the interpretation of much of the functions of certain organs, the existence of which had been known for many years, but the utility of which had been absolutely unknown, for example, the pituitary body, the thyroid gland, the suprarenal capsules, and others.

The knowledge of the functions of the liver and the spleen has been gradually increasing for a long time, and only by slow degrees have the current notions of the metabolic properties of these organs taken the place of the older ideas of secretion of bile and balance of weight. It has been, on the other hand, although the outcome of serious investigation, but also somewhat by a fortuitous concourse of thoughts and events, that the most astounding revelations of modern physiology have been made. What we have come to know amounts to this in general terms—that the absence of certain organs, of the functions of which, until quite recently, we knew nothing definite, leads to grave and diverse diseases of the body, whether this absence be brought about by surgical operation, or by disease more or less individual or specific in its character, and that, such being the case, the supply of the material of that organ as food, or some part of it, as an extract, to be introduced into the blood, removes the symptoms, acts with great promptitude, and, one might say, almost with some violence of disturbance of the whole economy. Not only so, but these extracts seem to possess a power reaching far beyond that which was first found to be their almost anticipated result—that is, in so modifying the action of the heart and the intravascular pressure, in a manner and to a degree entirely unlooked for, and requiring much further investigation; in order to unravel the true nature of the functions of those organs in health, and the value they may have, by their products, on the processes and treatment of disease. As yet we are only on the threshold of still greater discoveries in regard to life, but we see, through the portal, ranges of facts which are trustworthy guides as well as sign-posts, and which will, we believe, lead us to a larger knowledge of those recondite processes of life in its most essential and characteristic features—namely, of the nutrition of all organs, of the way in which this is brought about, and of the interdependence of all tissues, so that, perhaps in a far higher sense than we have ever realized before, the truth may be revealed that "when one member suffers all the others suffer with it," and the reason of this may be explained.

A very obvious consideration which should "give us pause" in self-congratulation is this, that as in past days the functions of different parts of organs, the kidneys, for example, were more or less clearly separated

by physiologists no longer with us now; so we have seen recently that only certain portions of other organs have the physiologic effects just discovered, and thus that there may be in what we have regarded as much simpler organic components, even in quite simple tissues, some unconsidered element of function, some *sine quâ non* of healthy life, some missing link in the phenomena of disease, so that it behooves us to keep the mental eyes wide open, to clear away all films of prejudice or hasty complacency, to expect the unexpected, and so, without looking for it, to find our reward.

Not less important than the matter just referred to is the recent development in "microbiology" and "all that therein is." The "germ-theory" of disease is not new. When it commenced, and who has the credit of its begetting, is not known. Probably, like ancient and modern heroes, it had many parents, and as many homesteads. It is quite clear that the great Harvey entertained it. Years later it was a hobby ridden by many, but without much convincing proof.

The most important fact with regard to recent microbiologic research is the gradually increasing appreciation of the fact that these lower forms of life exert, not necessarily mischievous, but, indeed, benignant influences on the human body, and that although the mode of their operation is not fully explained, they take part in healthy processes, assisting normal functions, nay, indeed, it would seem sometimes producing them and warding off the malign effects of other influences to which we are habitually exposed. These bodies to which we are indebted for this aid operate partly by chemic action and partly by what we must call a vital process, and by their cultivation outside the human body and their modification by passing through other organisms can be made to exert a malign or a beneficial agency on man.

The third great revelation of the last twenty years is the wonderful protective and curative power of these living products. This, in a very wide sense, is not new. Of all the most powerful agents of destruction, the most violent have been derived from "living" things; they are to be found in the animal and vegetable worlds, not in the mineral. In their most terrible malignity—such as in snake-bite, glanders, or hydrophobia—these need no human skill for their development; they are prepared in the laboratory of Nature, and, alas, are only too ready to our hand. Next to these come the poisons of stinging things, and, after them, the more slowly operating and less deadly animal infections; some with indeed beneficial influence, as "vaccinia;" others with local effects on the skin, but not often great disturbance of the general health.

The vegetable kingdom can produce potent poisons, such as belladonna-berries, aconite-root and leaves, poppy-juice, and the ignatia bean; but in order to render these more deadly the hand of man has to come in and prepare nicotin, strychnin, morphin, and the like; just as it may produce from the mineral or quasi-mineral world such potent agents as hydrocyanic acid, concentrated acids, and other dealers of destruction.

The interest in these facts lies in the modern mode for their utilization. The great potency of living products has led to very fanciful notions in therapeutics; and there have been those who, to cure diseases of organs, have given portions of the same but healthy organs of animals or of man or other animals. Again, the idea has been pronounced that even excreta were useful drugs, and that the diseased organs of man might effect a cure of those supposed to be afflicted in like manner.

Curious as some of these details are, they are of real interest to us only as they lead up, through inoculation for smallpox, to Edward Jenner's discovery of vaccination, and then, through the researches of Pasteur and Brown-Séquard, to our present state and plane of knowledge. It would seem now that there is scarcely any limit to what may be expected in the cure or prevention of disease; and the most striking of all phenomena is, to my mind, the probability of rendering an animal immune by the introduction into its organism of a healthy constituent of the body of another. This, if fully confirmed, will be the greatest veritable triumph of therapeutic medicine, instituted and guided by extended inquiry into comparative anatomy, physiology, and pathology. As in the human race or species there exist, as is well known, what may be termed "idiosyncrasies"—by which is simply meant that as a matter of fact some people, and some people's families, escape epidemic diseases, whereas they are especially prone to take others to which they may be exposed—so in the great economy of Nature certain groups of animals have been shown to exhibit no capacity for "taking," or for even being "inoculated" with the poisons to which others are exposed, and from which they suffer, and that severely. It would seem, therefore, that use may be made of these animals, more or less naturally immune from certain maladies, and that their immunity may be partially conferred on man.

Quite recently a communication of the greatest importance has been made on the rendering of animals immune against the venom of the cobra and other snakes, and on the antidotal properties of the blood-serum of immunized animals. This subject has occupied attention during the last six years, and we must all look forward with expectancy and hope to the possible and probable diminution of a great national and imperial calamity.

The outcome of all this is that the scattered fragments of knowledge and "guesses of truth" of many years have been gathered into a focus during the past twenty-five years; that the vegetable life, extracting from the mineral world the materials it needs for growth and the production of powerful agencies for good in the form of food and medicines, and for evil in the form of poisons, has given itself up to the growth of animal life, with its much more complex organs, and for the cure of ills once thought beyond the reach of human aid; but that, thanks to man's scientific ardor and industry, it has again shown itself to be our servant, our helper, and our protector.

These are not dreams of the study, they are facts of the laboratory and of daily life; and in using that word "life" again, emphasis is to be laid upon the belief that it is to living agencies and their employment that we must look for help in the care of infancy, the conduct of education—moral, mental, and physical—the training up of character as well as of limbs; that it is the guidance of living functions, in the choice of living occupations, be they either of hard work or of amusement; it is to these we must appeal if we would see the *mens sana in corpore sano;* and then it will be to these

that we may confidently look for help when the inroads of age or of disease are at hand, often to cure us of our trouble; or, if not, to give us rest and peace.

Speaking of the "professional" life, it was said that as physicians and surgeons, however numerous, we do not constitute a "body" of men unless we have some one prevailing spirit, common to us all. The profession may include its thousands and tens of thousands, but it is a crowd, a multitude, or a "mob," unless there is in it an *esprit de corps;* and, thanks to our great seats of learning, our universities and colleges, we have developed this uniting spirit now for many years. But our own special colleges of physicans and surgeons, our medical societies, and especially this vast Association, have done more within the last fifty years to give real, unifying life to its individual members than was possible, or even expected to be possible, by our forefathers.

That so large a body of men should be banded together under one common name means that they have some common purpose and some common plan of cooperation to attain it.

What that purpose is we know, namely, to render our profession of the highest service, not only to the individual but to the State, by taking our share and giving our advice in the making of our laws, so far as they affect us, as members of our profession; by the regulation of our charities; the guidance and control of labor; the care of the pauper and the pauper child; the lunatic and the quasi-lunatic, or the habitual drunkard; by the care of our poorer brethren; by the advance of scientific researches, and especially of those that require combined efforts and combined funds for their prosecution; by the promotion of useful and stable literature; and by the elevation of all that constitutes the education of the man of science, the physician, the surgeon, or the guardian of the public health.

These noble purposes cannot be achieved, nor have any of them been carried to any useful extent, without self-sacrifice, as well as the sacrifice of time; without a consideration of the views of others as well as an assertion of one's own; without respectful regard to the feelings and positions of our colleagues, as well as a due estimation of those which we may occupy; without patience as well as work; and an all-pervading sense of hope, in the midst of trying times and in the darkest hours. One thing, in addition, we should all most strenuously try to do, and that is to avoid waste of time. We may use it, or sacrifice it freely, but we cannot afford to throw away one moment; whether it be on personal ends, forlorn hopes, foregone conclusions, or threshed-out heaps of seedless fagots.

Outside our professional life, but closely mixed with our daily work, is the "social" constitution, or, as some would call it, the "environment" in which we have "to live and move and have our being." Certainly it has changed much within the last twenty years, and it would be impossible to say in what ways we have advanced, and in what others we have either retrograded or gone far, far out of the beaten track. The changes are on all hands, are pressing, importunate, and overbearing.

It would seem as if "reverence, that angel of the world," had from some regions taken flight, and that in her place were idols, or mocking shadows, or gorgeously apparelled lay figures. This absence of reverence shows itself everywhere, but, perhaps, it is possible to classify even such a negative quality and put its leading features under three great categories: (*a*) reverence for all that constitutes the religious element in life; (*b*) for that which is the groundwork of "social" propriety, and one may say even of decency, as our predecessors would have thought; and (*c*) for the constituted order of relative dignity in "family" life.

Finally, reference was made to the conduct of our profession to the "religious" element in our nature. Here we have nothing whatever to do with creeds, be they hoary with age or flushed with the bloom of youth; as members of the medical profession, we have to deal with those to whom these creeds mean much, and are, with what they entail to many, the be-all and end-all of existence. In giving the help we hope and ought to give to suffering and sorrowing man, we should do nothing worthy of the name unless we realize, and that to the full, the importance of this factor in our lives and theirs; and so guide its operation as to help it to chasten, subdue, control, and comfort those to whom it is the minister that they feel to be sent from God to help them in their passage through this region of passing shadows to that of realities which are abiding things.

(To be continued.)

Food-adulteration.—The following is the text of an Act passed by the Pennsylvania Legislature at its last session and approved by the Governor:

An Act to provide against the adulteration of food and providing for the enforcement thereof.

Section 1. Be it enacted, etc., that no person shall within this State manufacture for sale, offer for sale, or sell any article of food which is adulterated within the meaning of this Act.

Sec. 2. The term "food" as used herein shall include all articles used for food or drink by man, whether simple, mixed, or compound.

Sec. 3. An article shall be deemed to be adulterated within the meaning of this Act.

(*a*) In the case of food: (1) If any substance or substances have been mixed with it so as to lower or depreciate or injuriously affect its quality, strength, or purity. (2) If any inferior or cheaper substance or substances have been substituted wholly or in part for it. (3) If any valuable or necessary constituent or ingredient has been wholly or in part abstracted from it. (4) If it is an imitation of or is sold under the name of another article. (5) If it consists wholly or in part of a diseased, decomposed, infected, tainted, or rotten animal or vegetable substance or article, whether manufactured or not—or in case of milk if it is the product of a diseased animal. (6) If it is colored, coated, polished, or powdered, whereby damage or inferiority is concealed, or if by any means it is made to appear better or of greater value than it really is. (7) If it contains any added substance or ingredient which is poisonous or injurious to health. *Provided*, that the provisions of this Act shall not apply to mixtures or compounds recognized as ordinary articles or ingredients of articles of food if each and every package sold or offered for sale be dis-

tinctly labelled as mixtures or compounds, and are not injurious to health.

SEC. 4. Every person manufacturing, offering, or exposing for sale, or delivering to a purchaser any article of food included in the provisions of this Act shall furnish to any person interested or demanding the same who shall apply to him for the purpose and shall tender him the value of the same, a sample sufficient for the analysis of any such article of food which is in his possession.

SEC. 5. Whoever refuses to comply upon demand with the requirements of Section 4 and whoever violates any of the provisions of this Act shall be guilty of a misdemeanor, and upon conviction shall be fined not exceeding one-hundred nor less than fifty dollars, or imprisoned not exceeding ninety nor less than thirty days, or both; and any person found guilty of manufacturing, offering for sale, or selling any adulterated article of food under the provisions of this Act shall be adjudged to pay in addition to the penalties herein provided for all necessary costs and expenses incurred in inspecting and analyzing such adulterated articles of which said person may have been found guilty of manufacturing, selling, or offering for sale. *Provided*, that all penalties and costs for the violation of the provisions of this Act shall be paid to the Dairy and Food Commissioner or his agent, and by him paid into the State Treasury, to be kept as a fund separate and apart for the use of the Department of Agriculture for the enforcement of this Act, and to be drawn out upon warrant signed by the Secretary of Agriculture and the Auditor-General.

SEC. 6. The agent of the Department of Agriculture, known as the Dairy and Food Commissioner of this State, shall be charged with the enforcement of all the provisions of this Act, and shall have the same power to enforce the provisions of this Act that is given him to enforce the provisions of the Act by which he receives his appointment.

International Conference of Railway and Steamship Sanitation.—The measures taken in different countries to protect the lives of employés of railways and steamships and to guard their sanitary interests differ widely, and are insufficient in some respects. For this reason it has appeared desirable to organize an international conference of medical men interested in these matters, and the first will be held in Amsterdam, September 20 and 21, 1895. The committee of organization has divided the work of the conference into three sections: (1) The protection of the employés; (2) the medical organization; (3) the hygienic interests of employés and passengers. The committee has prepared a report of what has been done in these directions in Holland, either by the government or by the transportation-companies, and hopes that similar reports will be made by the representatives of other governments and companies for purposes of comparison and improvement. In view of the international importance of a number of questions to be considered, the committee invites governments and railway and navigation-companies to select representatives to the conference, and to send their names, together with the titles of communications to be presented, to the General Secretary, Dr. Pijnappel, Stadhouderskade 60, Amsterdam, before September 1st. Members of the conference will pay a fee of 5 florins ($2). The official languages will be French, English, and German. Prof. H. Snellen will be the presiding officer.

THE PREVENTION OF MASTOID EMPYEMA.[1]

BY CHARLES H. BURNETT, M.D.,
AURAL SURGEON TO THE PRESBYTERIAN HOSPITAL, ETC., PHILADELPHIA.

MUCH that is interesting and valuable has been written upon so-called "mastoid disease" and its treatment, but little or nothing on its prevention. This tends to spread abroad and foster the idea in the minds of the general profession that mastoid disease—*i. e.*, mastoid empyema and caries—is almost a necessary consequence of an otitis media, whereas quite the reverse is the truth. The subject naturally divides itself into the consideration of acute and chronic mastoid empyema.

It is highly probable that in every case of acute otitis media purulenta there is some involvement of the mastoid antrum in the inflammatory process; but this, like the acute inflammation in the tympanic cavity, will get well if not secondarily infected from without by improper treatment. Hence the prevention of mastoid empyema in cases of acute otitis media resolves itself into the prevention of secondary infection of the acutely inflamed middle ear.

It is the duty of the members of this Society to inculcate the idea that the proper treatment of an acute otitis media is largely negative, after either spontaneous or artificial opening in the membrana has occurred and a discharge set in. The inflammation of the middle ear being due to pathogenic germs (streptococci) in the middle ear, to which they have gained access from the naso-pharynx, the endeavor on the part of Nature, generally successful, is to afford them an exit from the tympanum by a spontaneous rupture of the membrana. Then a natural siphonic action sets in, which empties the mastoid antrum and saves the mastoid cavity, if this siphonic current is not stopped by irritative interference.

However, inspissation of the lateral portion of the exudate lying against the inner surface of the membrana, or previous thickening of the membrana, often delays and sometimes prevents spontaneous rupture of this diaphragm. Pain continues, the exudation is dammed backward toward the antrum, and if paracentesis is not now performed within twelve hours of the beginning of the earache, a mastoid empyema may be the result.

It follows, therefore, from what has just been said of the origin and progress of an acute otitis media, that all forms of inflation of the tympana should be carefully avoided in this disease, not only for the welfare of the ear already infected with pathogenic germs, but also in order to avoid forcing similar germs, into the, as yet, unaffected ear. In fact, in many cases of acute otitis media the disease in the middle ear is often a secondary result of the treatment of the naso-pharyngeal disease, rather than of the latter disease itself. It will be found, when an acute otitis media occurs a week after the ear on the opposite side has been inflamed, that this result is due to the numerous inflations of the tympana that, unfortunately, most of us have been taught to practise as part of a routine treatment of an acute otitis media. I have long since found it advisable *never* to inflate the ear, by *any* method, in either acute nasal or aural disease, because it has proved to be both painful and injurious.

I do not believe it is possible to abort an acute otitis media excepting by a paracentesis of the membrana in the early congestive stage. Sometimes congestion of the auditory canal and of the membrana undergoes spontaneous resolution, in spite of the ill-judged treatment it often receives. In acute otitis *dry heat* will never do any harm and may give relief. An instillation of ten drops of a warm, watery solution of carbolic acid[1] (2 per cent.) or of mercuric chlorid (1:10,000) may also give relief, if the congested membrana can endure the mechanical presence of such a column of fluid, which, I have observed, it rarely can. Such applications, however, tend to destroy staphylococci, always present in the auditory canal, and thus render the middle ear less liable to secondary infection through the perforation in the membrana when it occurs. As soon as the membrana is perforated and a discharge sets in, or even before this takes place, immediately after paracentesis, we should urge the medical attendant to insert simply a strip of iodoform-gauze or carbolic-acid gauze, an inch-and-a-half long by a quarter-of-an-inch wide, into the auditory canal, for antiseptic drainage-purposes, place a tuft of the same gauze in the concha, and

[1] Presented at the Twenty-eighth Annual Meeting of the American Otological Society, New London, Conn., July 16, 1895.

[1] Not with glycerol, as this neutralizes the effect of carbolic acid.

let the ear alone for twenty-four hours, when the same kind of dressing may be reapplied if the previous dressings are moist, or let alone for twenty-four hours longer, if they are dry. At no time do I syringe the acutely inflamed ear or put anything into it but the dressing mentioned, and I find that the middle ear heals rapidly and the perforation closes. We should strenuously diffuse the idea that all insufflations, moppings, syringings, and instillations, of anything, will now be irritant to the membrana and middle ear, and tend to bring about secondary infection.

We have all seen cases of acute otitis media, treated in the old way by putting various medicaments into the ears, turned into chronic cases, both with and without mastoid involvement; whereas an acute otitis media properly treated is never followed by mastoid involvement, or a continuance of discharge from the ear, but gets well in five or six days.

Since January of this year I have seen in consultation six cases of mastoid empyema, one chronic and five acute, *all* the result of improper treatment of the primary otitis media, by syringing with hydrogen dioxid, insufflation of boric acid, inflation of the tympana, etc.

The members of this Society should spread abroad the valuable knowledge that if dry heat gives no relief to pain, then the only other proper thing to do in acute otitis media is promptly to incise the membrana, preferably under ether. Then drain the canal antiseptically as described, and let the ear alone. We thus can prevent mastoid empyema. Schwartze was the first to sound the note of warning against secondary infection of the mastoid by insufflation of boric acid in acute otitis media, and Gradenigo and Pes[1] have recently written what must ever stand as a classic guide in the rational treatment of acute otitis media, in which they urge what in substance I have presented in this paper. Lermoyez and Helme,[2] too, have shown that even the cotton-tuft on the cotton-holder, twisted by the cleanest of fingers, is loaded with staphylococci, and should be subjected to sterilizing processes before being inserted into the ear.

In the face of all this wise teaching, it is most regretable that many of the younger aurists and some general practitioners are apparently vying with one another in their devices for pumpings, syringings, blowings, swabbings, etc., applied to the naso-pharynx and middle ears in acute otitis media. It is not surprising, therefore, that the number of cases of acute mastoid empyema is increasing, and that reports of such cases come in from all quarters, the writers and reporters apparently unconscious that they are detailing the secondary results of their own irritant and infectious treatment, applied either by way of the naso-pharynx or external ear, or by that unfortunately infectious procedure, in the absence of suppuration beneath the mastoid tissues, the so-called Wilde's incision, and, in some cases, by setons, even in this era of antisepsis.

If acute mastoid empyema is not prevented, necessarily we must all continue to observe chronic otorrhea and chronic mastoid empyema. Here, too, the treatment resolves itself into one directed primarily to the middle ear. Chronic mastoid empyema cannot be cured until the chronic tympanic purulency is arrested. Mastoid trepanation in chronic mastoid empyema, without exposure of the middle-ear cavity and removal of carious and necrotic tissues, is valueless in all instances, even in intracranial lesions, for if the tympanic cavity is allowed to remain more or less full of the carious and infective tissues from which the mastoid caries, the sinus-thrombosis, or the cerebral abscess has arisen, not one of these diseases is radically cured until the infectious nidus in the middle ear is destroyed.

Mastoid trepanation alone does not check chronic otorrhea. The necrotic tympanic tissues must be removed before the chronic purulency is checked. This is a common observation, not only in mastoid caries, but in intracranial, cervical, and pharyngeal lesions of otitic origin. No operation on the neck or within the cranium in such cases, though it may immediately save the life of the patient, may be of permanent value so long as necrotic tissues are left in the middle ear. This fact aurists should keep before the minds of the profession. But far better than any directions for the cure of mastoid empyema is the proclamation of methods of prevention.

REMOVAL OF THE APPENDAGES AND LIGATION OF THE UTERINE ARTERY TO THE UTERO-CERVICAL JUNCTION.

Report of Forty-five Cases of a New Operation.

BY F. BYRON ROBINSON, M.D.,
OF CHICAGO, ILL.

I introduced the operation of removing the uterine appendages and ligating the uterine artery to the utero-cervical junction about two years ago. The technique consists in ligating the appendages and then snipping them off. An aneurism-needle, armed with a double ligature, is then passed through the broad ligament at the cervico-uterine junction on the inner side of the uterine artery. The one ligature is tied along the side of the uterus, including the perpendicular

arteries of the uterus, the Fallopian tube, and the round and ovarian ligaments. The other ligature is tied on the broad ligament, including the infundibulo-pelvic ligament. Another method consists in ligating and removing the appendages, and then simply ligating the uterine artery once or twice as it courses through the broad ligament by the side of the uterus as low down as the neck.

The first method is the best, as it results in atrophy not only of the bloodvessels, but also of the nerves and ganglia. I have ligated the uterine artery down to the cervico-uterine junction in nearly all of my forty-five cases. No symptoms of tissue-death in the uterus have so far appeared in any of the cases. In some pain is severe for from twenty-four to forty-eight hours, but it seems due to trauma by the ligatures on large numbers of nerves and ganglia. This pain can be quieted with gr. $\frac{1}{16}$ morphin once or twice, for that of greatest severity is generally over in fifteen hours. This operation can be widely applied in surgical gynecology. It produces sufficient shock on the circulatory and nervous apparatus quickly to cause atrophy of growing uterine myomata. The effect of ligating the uterine arteries as they course through the broad ligament is to cause rapid atrophy of the endometrium, checking endometrial secretions and hemorrhage. The pelvic floor is preserved intact by this operation, obviating the danger of vaginal hernia. A vaginal hysterectomy, performed by Dr. Lucy Waite, with my assistance, was followed in several months by a vaginal hernia.

The operation under consideration brings on the menopause rapidly. The latter followed in two months in one case. The operation leaves a functionless, atrophic uterus, in normal position, which so far among my patients has occasioned no trouble. This report is based on forty-five operations, performed during the last twenty-six months. In several of the cases I assisted Dr. Lucy Waite and Dr. Bertha Van Hoosen, and include these in the report. The utility of the operation resides in the following points: (1) it checks hemorrhage; (2) it arrests menstruation; (3) it elevates the uterus; (4) it causes shrinking of the uterus; (5) it avoids the removal of uterine myoma; (6) it avoids vaginal hernia.

We have proved that the operation is suitable to every one of the foregoing six propositions. Dr. Van Hoosen reports that menstruation has not reappeared in any of the cases in which I assisted her in operating. I know of not a single case in which Dr. Waite and I operated in which menstruation continued. We removed the appendages and tied the uterine arteries in a patient thirty-seven years old, with a myoma extending above the pelvic brim. Three months later the tumor was decreased in size one-half; eight months later the uterus is what I should term almost normal in size. The operation causes shrinking of the inflamed uterus, which is nearly always associated with suppurating appendages, and as a result excessive secretions are checked. I have, time after time, by subsequent examination, proved the shrinking or atrophying of the large, hard, inflamed uterus. The operation elevates the retroverted uterus, and maintains it in position. It is superior to hysteropexy, as it leaves a movable uterus.

Eight months ago I operated with Dr. Verity, of Chicago, in a case with diseased appendages, and with a large, hard, retroverted, inflamed uterus. We removed the appendages and tied the uterine arteries almost down to the cervix. Eight weeks subsequent to the operation I examined the patient, and the uterus was in a distinctly normal position. It was movable, and shrunken at least one-third in size. As the months go by I am examining the patients operated on. I find that the large uteri, with myomata and subinvolution, have all shrunk to normal and less than normal. Large uteri that required space outside of the pelvis are now equal to a normal uterus, or even less in size. Menstruation has not ceased entirely in every one of the forty-five cases, but in only two or three is there a slight flow, and in such cases some old inflammation has recurred. The removal of appendages does not always cure a uterus infected and chronically inflamed; but the operation is applicable to the six propositions stated. Two objections may be raised against the operation: (1) the danger of gangrene; (2) the ligation of so much tissue.

I do not consider it an objection that one might penetrate the bladder with a ligature-armed needle, or that a ureter might be included in the ligature, as any other operation is encumbered with similar dangers. The idea that the ligatures might become infected and lead to subsequent fistulæ is not a serious objection. I would suggest that the ligature which includes the broad ligament should not include the Fallopian tube with its mucous membrane, as that might enhance the chances of suppuration. The needle could be passed just beneath the tube. This method ought not to protract the operation more than ten minutes. Among forty-five cases one patient died from the results of the operation. This patient was a weak and worn-out woman of thirty-seven years of age, who had had a myomatous tumor for six years. The broad ligament was tied in sections, and the tumor shrunk so rigidly in four days that it produced a kink in the bowel by dragging on it. The bowel was not completely obstructed. The patient went on well for four days, after which she suddenly sank in a few hours, without any symptoms. An autopsy revealed the fact that in four days the tumor had shrunk enor-

mously, and a kink was found in the bowel. The debility of the patient and the worn-out nervous centers were to blame for this death. The other death among the forty-five cases was due to urinary suppression on the sixth day in a woman who had almost flowed to death during six years with a large uterine myoma. The case progressed well for six days after the operation, when the urine ceased to be secreted, and the patient died about thirty-six hours later.

CLINICAL LECTURE.

VESICULAR EMPHYSEMA.

By CHARLES G. STOCKTON, M.D.,
OF BUFFALO, N. Y.;
PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE IN THE UNIVERSITY OF BUFFALO; PHYSICIAN TO THE BUFFALO GENERAL HOSPITAL

LET us begin the study of this case with a little practice in the art of observing symptoms. The child is an Italian who came to this country in infancy. The mother said that when still an infant the child had difficulty in breathing and had spells of wheezing, and at times of coughing. She has continned to present these symptoms, and now, at the age of eight years, although fairly well developed, shows some peculiarities of interest in the study of her disease.

You will notice that the child has a short neck, owing to the encroachment of the trunk. She is somewhat round-shouldered; the scapulæ project; the ribs arch out under the scapulæ; and the chest in front is quite round. The ribs are comparatively horizontal and the intercostal spaces are ill defined. You will note further that the child breathes hurriedly, and, in spite of this, oxygenation is imperfect, as shown by the lividity of the lips and face, which is apparent even through the tawny Italian complexion. The abdomen is somewhat prominent and the type of respiration is largely abdominal, the chest being comparatively fixed. All this shows that Nature is doing her best to get air into the lungs and make oxygenation as nearly perfect as possible, but she, nevertheless, fails. Coming near the child you can hear the wheezing, and on auscultation of the chest there is marked sibilant breathing and occasionally sonorous breathing. Listening still more closely one can detect a relative loss of vesicular character in the respiration. There is to be heard over the larger tubes the blowing sound which is normal, but this sound is more diffused in her case, as it is not masked, as it naturally is, by the finer sounds of vesicular breathing.

Here is an instance in which a diagnosis can be made by the direct method. To make it still plainer that the chest is distended with air, let me practise percussion. Note how marked the resonance is. The condition is that of a chest full of air in a child embarrassed for want of air. The paradox can be explained only by adding that the lungs are filled with residual air, not with air coming and going with each respiratory act. It is an instance of vesicular emphysema, a disease not often seen in childhood; but when it does occur early in life, before the bones have became firm, we see the classic picture of a barrel-shaped chest. Besides emphysema, the child has a certain amount of bronchitis, at present limited, but at times becoming greater. She has also asthma. This group, emphysema, bronchitis, asthma, is frequently found. Any of the three may come first. Which has been the first here? Undoubtedly the emphysema. In some lungs there is a faulty development or a fibroid degeneration of tissue, so that the lung loses its elasticity, and, not being able to empty itself, the air-cells remain constantly distended, while only a modicum of air passes in and out. In such cases emphysema comes first, without any predisposing bronchitis or asthma. The condition is sometimes hereditary, sometimes acquired, but not susceptible of perfect explanation. The results of this condition of the lungs are hence easily understood. The ribs are pushed out into a nearly horizontal direction; the intercostal spaces may actually bulge. The abdomen and neck are encroached upon in the efforts that Nature makes to enlarge the capacity of the lungs.

After a time the degeneration progresses so far that numberless little air-sacs fuse together, not from the suppuration of their walls, but from slow, non-inflammatory degeneration. This process may go on throughout both lungs, or one lung or even a part of a lung may be more particularly involved. Sometimes this fusion proceeds to the formation of air-spaces as large as the end of the thumb, and, in spite of their size, these air-spaces have very little function in respiration. Meantime the capillaries of the lung become obstructed because of the pressure upon them by the air-spaces, and also from disease of the vessel-walls. In consequence of this obstruction to the free flow of blood through the lungs, the right side of the heart becomes distended, and, later, the viscera generally become engorged with venous blood. Thus there results passive congestion of the liver, kidneys, stomach, and intestines, while the extremities are blue and the lips livid. The lack of oxygen gives rises to numerous changes throughout the body, and the fibroid degeneration that occurred in the lungs primarily may often also be observed in the liver, kidneys, and various other organs.

The treatment for this condition, so far as drugs are concerned, I shall not mention. The child should receive appropriate medication for the asthma and bronchitis as they may occur. There is no medicinal treatment for emphysema. The pneumatic cabinet has been suggested, allowing the patient to breathe condensed air and expire into a partial vacuum. The result, however, is questionable. The child should lead a quiet life. Exercise only aggravates the difficulty, increases the tension on the right side of the heart, and leads to the train of symptoms depending on venous congestion.

CLINICAL MEMORANDA.

GUNSHOT-INJURY OF THE BRAIN[1]

Involving the Left Third Frontal Convolution, without Aphasia.

By C. S. HOFFMAN, M.D.,
OF KEYSER, W. VA.

D. F., aged twenty-eight years, on the 22d day of October, 1894, while in a state of temporary melancholia, attempted to end his existence by shooting himself through the head. I saw him in a few minutes

[1] Read before the West Virginia State Medical Association, June 28, 1895.

after he was shot. He was then sitting upright in a chair, with blood flowing from a wound in the left temple. He was pale, and evidently suffering from shock. His mind was dazed. He recognized me, however, called me by name, but was unable to tell correctly how he was hurt, or where he boarded, but when the name of the house at which he boarded was suggested he said yes, that was the place, and without any hesitancy distinctly mentioned the proprietor's name.

Examination revealed a pistolshot-wound in the left temple, into which I could introduce the end of my little finger. There was no paralysis. The man was able to walk with little assistance to his boarding-house, about one square distant. I had him put to bed, and cold applied to his head, thinking from the position and nature of the wound that he would soon join the majority. In two hours I saw him again. He still recognized me, called my name without any hesitancy, also recognized other persons in the room and called their names. His pulse and respiration were about normal. His condition up to this time was that of a person suffering from concussion instead of injury to the brain. There was still no paralysis. With my finger and probe I detected loose bone on the inside of the skull, but I was unable to locate the ball. About a teaspoonful of brain-substance had oozed from the wound. Dr. Spear, of Cumberland, now saw the case with me. We decided upon an operation. Accordingly, as soon as everything could be made ready the patient was chloroformed, and with the assistance of Dr. Spear, of Cumberland, and Dr. Hall, of Keyser, I enlarged the wound in the scalp and exposed the skull. There was almost a round hole in the external table of the skull, but the inner table was badly broken, and some of the fragments of bone were loose and driven in the brain, while others were partially attached to the skull and dura mater, their free rough edges being turned in upon the brain. These fragments were all removed, and the edges of the skull smoothed off. Search was made for the ball, but it could not be located, although I passed a probe four inches into what I supposed was the track of the ball, and also passed my little finger in, but without success. The wound was cleansed, dried with iodoform-gauze, and then a piece of iodoform-gauze was passed well into wound for drainage. The wound was dressed antiseptically, but suppuration took place in the scalp-wound, and the dressing had to be changed every day. The wound healed by granulation. There was no appreciable pus from the interior of the skull.

The patient remained under my care from October 22d, the time of the accident, until November 15th, in all twenty-four days. The highest temperature was 101°. This occurred on the fourth, sixth, and twelfth days after the injury. The highest pulse-record was 106, but the average was about 80. On and after the thirteenth day from the injury pulse and temperature remained normal. The patient was very restless for the first three days, requiring at times restraint to keep him in bed. For this morphin sulphate, chloral hydrate, and potassium bromid were given with good effect. After this time the patient became somnolent, passing urine and feces in bed. He was, however, easily awakened to take milk. Five days after the injury he could give intelligent answers to some questions. About a week before he left my care he could sit up, and began to take interest in what was passing in the room, and would usually tell when he wanted to pass urine and feces.

The place of the wound is readily discernible. While ossification seems to have occurred, there is a depression where the ball entered. The entrance of the ball, as can be seen by this depression, is about one-and-a-half inches posterior to the external angle of the left orbit, and about three-quarters of an inch above a horizontal line passing through the external angle of this orbit, making the wound very near the center of the temple, and directly over the part localized as the center of speech. The course of the ball was slightly upward and backward. In connection with the wound in the left temple it is to be noted that the man is left-handed. The pistol with which the wound was inflicted is a thirty-two caliber. I here show you six pieces of bone, and regret that I have either lost or mislaid the original ones. These, I feel certain, are about the size of the pieces removed, and will give an idea of the extent of the injury to the skull. Laying these bones side by side they will cover at least one square inch of surface. The pistol was evidently held very close against the head, as the hair was burned, but there were scarcely any powder-stains in the skin. Considerable powder-stain was, however, present in the bone and brain.

It is not my purpose to enter into a general history or a discussion of the treatment of gunshot-injury of the brain, as this is accessible through our text-books on the subject; but there are some very interesting features of this case to which I desire especially to direct attention, viz.: That the prognosis in this case, without an operation and the removal of the pieces of broken bone, must have been fatal; that the result would indicate that it was good surgery not to make too great an effort to extract the ball; that a man can shoot himself in such a vital spot as this and not be instantly killed; that the man was not even rendered wholly unconscious; that he made an excellent recovery, and now, at the expiration of eight months, is apparently well, and able to transact business and do bodily labor, although he still carries the bullet in his brain, and lost at least a tablespoonful of brain-matter; that there was no paralysis of any member of the body; that there was no evidence of aphasia, although the ball must have injured the third left frontal convolution of the brain, and in our efforts to remove the pieces of bone we also must have injured this convolution. This is a matter of interest to which I would especially call attention. It is true that while the man was suffering from the acute inflammatory effects of the traumatism he could not answer intelligently, but there was no time when he was conscious that he had any difficulty in pronouncing words or forming sentences. At times he was a little absent-minded. Before he was injured he was always manifesting an uneasiness about succeeding in life. Since the accident I think he shows less of this disposition.

In the great majority of mankind the center of speech is located in the left hemisphere of the cerebrum and in the third frontal convolution; still there are exceptions, as cases have been observed of left-handed persons who lost their power of speech after a lesion of the right hemisphere. As this man is left-handed, it is fair to ask, May not the center of speech in this man be located on the right side, and may not this explain the absence of aphasia?

TWO CASES OF BILATERAL CASTRATION FOR ENLARGED PROSTATE.

BY A. H. LEVINGS, M.D.,
OF MILWAUKEE;
PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY AND CLINICAL SURGERY IN THE WISCONSIN COLLEGE OF PHYSICIANS AND SURGEONS, SURGEON TO THE PRESBYTERIAN HOSPITAL.

WHILE the subject of castration for enlargement of the prostate is exciting so much discussion, the report of the following cases may not be without interest:

CASE I.—J. B., aged seventy-seven years, was obliged to resort to the use of the catheter eighteen years ago, on account of an enlarged prostate and the consequent inability to pass his urine. The catheter was used for thirteen years, during which time he was never able to pass urine without its aid. During the last year of his catheter-life increasing difficulty was experienced in passing the catheter, until it finally became impossible to enter the bladder with any instrument. At this juncture—five years ago—a suprapubic cystotomy was performed and an artificial urethra established. For three or four years immediately following this operation the condition of the patient seemed satisfactory. Then he commenced to complain much of pain; his cystitis grew worse, and repeated rectal examination established the fact that the prostate was constantly increasing in size. At this time I advised castration, which was performed at the Presbyterian Hospital, May 14, 1895. At the time of operation the prostate was as large as a cocoanut.

On June 20th, thirty-six days afterward, Mr. B. passed a small stream of urine by the urethra, the first time for eighteen years. He has continued to do this every day since, with increasing size of stream, and for the past week he has only used his suprapubic urethra night and morning, when the bladder was irrigated. As nearly as I am able to determine by rectal examination, the prostate has diminished in size about one-half, the cystitis is much improved, and the severe pains are practically gone.

CASE II.—Mr. A., aged fifty-one years, entered the Presbyterian Hospital June 18, 1895, and gave the following history: On and after December 8, 1894, he was unable to pass his urine without the aid of a catheter. About the middle of December the right testicle became inflamed and suppurated; two weeks thereafter the left testicle also became inflamed and suppurated. He had been confined to his house constantly, and to his bed the major part of the time after the first attack in December, in consequence of the severe pain both in the testicles and bladder.

When Mr. A. entered the hospital he was much emaciated, and both testicles were enlarged, indurated, and nodular. On the right side of the scrotum were two fistulous tracts, and on the left one discharging pus. There were two ounces of residual urine, which was ammoniacal and contained a considerable quantity of pus. Both lobes of the prostate were very decidedly enlarged. The inflammation of the testicles was evidently tuberculous, and this fact, considered in connection with his enlarged prostate, made me advise castration, which was agreed to and performed June 23d. Recovery was uninterrupted. In two weeks the man was walking about the hospital, almost wholly free from pain; the urine had become acid and almost clear; a catheter was no longer necessary; and the residual urine had entirely disappeared.

On July 18th, by rectal examination, the left prostatic lobe was scarcely to be felt, while the right was much reduced in size. The patient was discharged in excellent condition.

Although I undertook both of these operations with some degree of misgiving as to the ultimate good to be attained, the results have been most satisfactory both to the patients and to myself. The decided improvement in the cystitis, the disappearance of the pain, the ability of the one again to pass urine by the urethra after eighteen years of absolute cessation, and the disappearance of the residual urine in the other, with atrophy of the prostate, are conditions concerning which I believe there can be no doubt.

It would seem that after castrating thousands upon thousands of women in the prime of life, often, I fear, upon the slightest pretext, it is hardly consistent to hold up our hands in horror at the idea of castrating some men at an advanced age for the relief of an otherwise incurable and most distressing condition, if the operation should offer a reasonable hope for a permanent cure.

459 VAN BUREN STREET.

VESICO-VAGINAL FISTULA—SUTURE OF BLADDER WITH CATGUT.

BY J. J. BROWNSON, M.D.,
OF DUBUQUE, IOWA.

MRS. D. L. F., aged thirty-two years, the mother of four children, came under my care to be operated upon for a vesico-vaginal fistula. Her history was good, with the exception of some difficulty in micturition during childhood, the precise nature of which I was unable to learn. The story of the case as narrated by the patient is as follows: About two years ago she lived upon a farm in Minnesota, and her home was about ten miles from the nearest village. While residing at that place she was confined with her fourth child. The labor passed all right, but she had retention of urine following it. The physician in attendance, after visiting her for several days for the purpose of using the catheter, said that he would be unable to attend her any longer, and, as she would not or could not use the instrument herself, he made an opening from the vagina into the bladder through which the urine drained away.

The constant annoyance of the infirmity caused the woman to seek relief. Accordingly she was sent to the Mercy Hospital in this city to be prepared for operation.

Upon examination the urethra was found patulous and seemed natural. There was a fistula about three-fourths of an inch long in the vesico-vaginal septum. The uterus and vagina were otherwise normal.

The patient was taken to the operating-room, and, with the assistance of Drs. Boothby, McCarthy, and A. Staples, steps were taken to close the opening. The woman was placed in the usual position and a sound passed into the bladder up to the fistula to serve as a guide, while the tissues of the vagina and bladder were pared funnel-shaped so as to make a good-sized denuded surface on the vaginal side. When all was prepared it occurred to me that it would be a good idea to unite the mucous membrane of the bladder with catgut, and

this was done by means of a continuous suture. The tissues of the vagina were then sutured together with four silver wires. Having no sigmoid catheter a soft-rubber one was fastened in the bladder, and the vagina was packed with iodoform-gauze.

The after-treatment of the case progressed favorably until the third night, when the catheter slipped out. On the next morning a pint of urine was drawn off and the catheter reinserted; but it did not stay in well; so after the first week the retention of the instrument was abandoned altogether and the water drawn twice a day.

On the eighth day the urine was tinged with blood and remained so for two days. I was unable to account for this unless it was from the disintegration of the catgut stitches.

Nothing unusual presented itself from this time on. At the end of the third week the silver wires were removed. The wound had healed solidly. Not a drop of urine had escaped. In fact, after the stitches were removed it was difficult to see the exact site of the closure.

The patient was at this time requested to urinate in the natural way, but she maintained that she could not. The catheter was accordingly passed for one week longer, when, as the woman again refused to attempt to micturate, a large glass dilator was introduced into the urethra and allowed to remain for several minutes. Following this she was able to pass water, and has not complained of any trouble since. She is at present in good health, and, as it is several years since the operation was performed, the relief may be considered as permanent.

Of course, one cannot form conclusions from one case, but I think the suture of the bladder with catgut is a good feature, for the reason that it forms a double joint, preventing leakage of urine, and thus giving the vaginal tissues opportunity for union, while the possible objection, that should any of the catgut remain unabsorbed a calculus might result, would not seem warranted by the outcome of this case.

TOXICOLOGIC NOTE.

POISONING BY LYSOL.

By A. J. COMSTOCK, M.D.,
of Ventura, California.

The following facts in a case of accidental poisoning by lysol, occurring to one of my patients recently, are worthy of record:

The patient is a healthy woman, twenty-four years of age. Three days after her confinement she was given, by mistake of her nurse, one-and-a-half tablespoonfuls (fully six drams) of lysol, instead of the laxative ordered. The drug was taken early in the morning upon an entirely empty stomach, but was diluted with two ounces of coffee. The woman was immediately seized with violent burning pain in the mouth, throat, and stomach. It was forty-five minutes before a physician reached her, and in the meantime nothing in the way of a diluent or emetic had been administered, and vomiting had not occurred. Not being in town myself, another physician was called. He reached the patient forty-five minutes after the accident and at once administered oils, eggs, diluents, and emetics. She was then in a partially comatose state, very pale, perspiring profusely, and with the muscular system in a state of complete relaxation. Respiration was slow and shallow and the pulse imperceptible. As emesis did not readily occur, the physician returned to his office for a stomach-pump, but upon his return found the woman vomiting freely. The poison had then been retained two hours and forty-five minutes. After the vomiting consciousness partially returned, but the patient remained very weak. I first saw her three hours after the poison had been swallowed. She was then still partially unconscious, with great muscular relaxation, a very weak and rapid pulse, and the pupils widely dilated. I at once administered another emetic (gr. xx of ipecac in powder) and large quantities of warm water, until free emesis occurred, twelve minutes afterward. The woman was then given small and frequently repeated doses of magnesium sulphate until free purgation was produced. The after-treatment consisted of flaxseed-tea, bismuth, and restricted diet. The subsequent gastritis was slight, but for forty-eight hours there was partial suppression of urine, with albumin present in large amount. The albumin disappeared on the fourth day and the secretion of urine became re-established. It is now a week since the accident and the patient is apparently fully convalescent.

MEDICAL PROGRESS.

Fracture of the Lower Cervical Spine, with Coma.—Bell and Easterbrook (*Edinburgh Medical Journal*, July, 1895, p. 38) have reported the case of a laborer, thirty-one years old, who fell backward from the top of a loaded haycart, landing on the back of his head in a field. When found, lying on his back with his feet toward the cart, he was conscious and able to speak intelligently, complaining of pain between the shoulders, but was absolutely unable to move the trunk and limbs, with the exception of the shoulders. He remained in this condition for twenty-four hours, with slight twitchings of the shoulders and a considerable discharge like white of egg, stained with blood, from the mouth, independent of vomiting. He then became feverish and delirious, and in two or three hours lapsed into a state of apparent coma. Neither urine nor feces had been voided after the accident. Later there was incontinence of urine. The temperature rose to 106.5°, the pulse to 140, the respiration to 40 per minute. The patient gave vent to an occasional short cry, frowned slightly when the face was pinched, and made a faint effort to open the partially closed eyes when called loudly by name or when a bright light was held before him. There was complete loss of motion and sensation in the trunk and extremities; the face and neck were sensitive to touch and pain. Motor power was present in the muscles of the face and lower jaw, and in those of the neck connected with extraordinary respiration. The paralyzed muscles were flaccid. The superficial and deep reflexes were absent, with the exception of the cremasteric and conjunctival. The pupils were equal, markedly contracted, and non-reactive to light. There were also evanescent priapism, overflow incontinence of urine, relaxation of the anal sphincter, incontinence of feces, and a purely reflex deglutition. Lividity was easily

induced by pressure, and the toes were slightly glossy. The respiration was diphragmatic, aided by the muscles of the neck. At each expiration there occurred protrusion of the upper part of the abdomen, an indrawing of the lower intercostal spaces, a dragging down of the larynx and root of the tongue, a dilatation of the alæ nasi, and a tilting up of the chin. The expiration was sudden and gasping, the upper part of the chest rising with a jerk. The urine contained a slight amount of albumin. As the man lay supine, with his head flexed upon the pillow, a prominence could be felt above the last cervical spine, pressure over which elicited a pained frown. The prominence disappeared when the patient was turned on his right side. On digital examination of the posterior laryngeal wall, a slight ridge was detected opposite the root of the tongue. Examination of the ocular fundi disclosed no abnormality. Despite treatment with extension, ice-bags, leeches, and inhalations of oxygen, the patient failed to rally. Upon post-mortem examination a thin layer of extravasated blood was found between the epicranial aponeurosis and the pericranium, especially marked between the occipital and left parietal eminences. A very small quantity of blood-stained fluid escaped from the foramen magnum in removing the brain. No gross lesion of skull or brain was present. The spine presented no deformity. On dissection an extravasation of blood in the soft parts behind the lower cervical spine was found. In the spinal canal an extradural extravasation of blood, extending from the foramen magnum to the sixth dorsal vertebra, was present, being most marked in the lower cervical region. The body of the seventh cervical vertebra was the seat of a comminuted fracture and crush, the spinal cord being firmly nipped by the lower fragment, which was overlapped anteriorly by the upper.

THERAPEUTIC NOTES.

The Treatment of Diphtheria with the Antitoxin.—FÜRTH (*Münchener medicinische Wochenschrift*, 1895, No. 30, p. 689) reports the results obtained at the medical and surgical clinics at Freiburg in the treatment of 100 cases of diphtheria with the antitoxin between October 1, 1894, and June 5, 1895. During this period 115 cases came under observation. Of this number, fifteen were not treated with the antitoxin, two being received in a moribund condition, and the remaining thirteen from economic reasons. In all of the latter recovery ensued. Of the 100, bacteriologic examination was made in fifty-five, and diphtheria-bacilli found in fifty, rarely in pure culture but often associated with staphylococci and mostly with streptococci. In five cases diphtheria-bacilli were not found upon a single examination. In conjunction with the injection of the antitoxin other measures in usual employ at the clinics were not omitted. Thus, the air of the wards containing the severe cases was kept constantly moist by means of the steam-spray; local applications or insufflations of precipitated sulphur or of chinolinbenzyl rhodanate were made three or four times a day; children able to do so used potassium chlorate or potassium permanganate as a gargle, and inhaled frequently a solution of carbolic acid; an ice-collar was applied; bits of ice were swallowed when pain was present; and in cases of involvement of the nose irrigation of the nares with antiseptic solutions was practised. Among the 100 cases thus treated there were twelve deaths. The mortality from 1889 to 1894, with ordinary treatment, fluctuated between 31 and 49 per cent., averaging 39 per cent. The same average existed during the seven months of the year corresponding to the period during which the antitoxin was used. Forty-three of the 100 cases presented laryngeal involvement, and thirty-one required tracheotomy. Among the last number there were eleven deaths, 35.4 per cent. In previous years tracheotomy had been required in 46.2 per cent. of the cases, with a mortality of 70.4 per cent. The opinion is expressed that the antitoxin is a specific in the treatment of diphtheria with which no other therapeutic measure is to be compared.

The Treatment of Electric Shock.—The Berlin correspondent of the *Medical Press and Circular*, July 24, 1895, p. 84, quotes from the *Pharmazeutische Centralblatt* the following procedures to be adopted in cases of injury from powerful electric currents: The current should be shut off at once if the means are at hand, and the person called upon understands how to do it. If this cannot be done, care should be taken not to touch the injured person's body with the hand. If no India-rubber gloves are at hand, the body should be dragged away from the wires by grasping the clothing, or the coat should be taken off and folded (a dry cloth may be used for the purpose), when the injured person may be grasped through it and dragged away. When it is not possible to remove the injured person from the wires, that part of the body should be raised that is in contact with the earth or the wire from it, using the covered hand. This will break the current, and it will generally be possible then to get the body away. If this cannot be done, a dry cloth should be placed between the body and the ground, and then the body disentangled from the wires. If the body is freed from the wires, all the clothing should be removed from the neck and the injured person treated as one drowned. The mouth should be opened and the tongue covered with a cloth and grasped. The latter is pulled forward and gradually allowed to fall back. This movement should be repeated sixteen times a minute. Care should be taken that the root of the tongue is thoroughly moved. The bystanders should not be allowed to give the injured person spirit or wine.

The Treatment of Insolation with Quinin is recommended by BINZ (*Deutsche Milit.-ärztliche Zeitschr.*, April, 1895; *Berliner klin. Wochenschr.*, No. 29, p. 643), both from theoretic considerations and from the favorable results obtained by Anglo-Indian physicians. The best preparation is the bichlorid, which appears in fine colorless crystals readily soluble in water. The solution is strongly acid, but when injected into the corium causes no pain. The solution should be of such concentration that a syringeful contains gr. 3¾. This dose may be frequently repeated.

℞.—Quininæ bichloridi . . . ʒijss.

Solve in aquæ destillatæ ʒj. Filtra. The solution equals a volume of ʒx.

The Medical News.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM, IN ADVANCE $4.00
SINGLE COPIES 10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM . . . 7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,

PHILADELPHIA.

SATURDAY, AUGUST 17, 1895.

MAX NORDAU AND DEGENERATION.

Is it possible that in Max Nordau we have a real prophet calling to us in the wilderness, or have we only a fakir? These alternatives will be, and are being, answered each in the affirmative, for Nordau has at least the fortune of having caught the popular eye; the merit of having divided opinion; and, perhaps, may have the strength for yet founding a "school." In all these respects he is thoroughly up to date. There is enough of audacity and sensationalism in his views to meet even the demands of this "degenerate" age; enough of a spice of "mysticism" and obscurity in his criticism to keep him well abreast of all the symbolists galore; and enough of dogmatism and ferocity in his expression of opinions to put him well on a level with the egomaniacs. In other words, Max Nordau is, as he is so fond of describing others, somewhat *fin de siècle*.

But we take Max Nordau seriously—(a somewhat difficult thing to do in places)—and we think that we find in him some golden utterances as well as some obvious solecisms. The novelty—perhaps even the originality—of this writer consists in the fact that he has made a feint of devoting the methods and the data of the medical sciences, especially pathology and psychiatry, to the elucidation and correction of some of the prevailing tendencies and errors in art and literature. He has cast his book in the form of a medical treatise. The very boldness of this scheme has in a measure defeated its object, because it is evident, upon a close reading of the work, that neither the subject nor the author himself was yet ripe for such an enterprise. The grave defects of the scheme are, first, that the contemporary sciences of criticism and pathology have not yet advanced sufficiently to supply the necessary data; second, that they possibly never will advance thus far; third, that they have so little in common that they can play but little mutually into each other's hands; and, last, that Max Nordau, although he apparently has encyclopedic knowledge, has not yet attained that mastery of himself that would render him either a safe scientist or critic.

Let us consider these points. The science of criticism—if it is a science—is yet far from being established upon a satisfactory foundation. The best proof of this is found in the fact that in our present age glaring errors of taste and judgment in letters and art are exceedingly rampant. It is against these that Nordau wages incessant war. In a highly critical age such warfare would be uncalled for, because if criticism were a science, established upon secure foundations, as chemistry and astronomy are sciences, this ruck of contemporary literature would have been stifled in its birth. As chemistry and astronomy purify themselves constantly by rejecting error, so would literature if it had a science of criticism.

As for psychiatry, which is the branch of pathology upon which especially Nordau depends for his principles, it is obvious to all anthropologists that the time is yet far distant when this science will be able to dictate terms even to jurisprudence and sociology, much less to such a recondite subject as criticism. To attempt it now is premature; and the attempt must give Nordau's book the appearance of merely a pseudo-scientific treatise. The disguise cannot escape the penetrating eye of the student, and this is the gravest reproach that can be brought against Nordau.

The second defect of such a scheme is that it demands more than either of these sciences may ever be able to contribute. The purest ages in art and literature received no aid from either criticism or psychiatry. If the time ever comes when the cultivation of these humanities shall depend upon the warning voice of psychiatry, or even the support

and defence of a scientific criticism, then the history of humanity must reverse itself. Criticism is no more productive than is psychiatry itself; both deal rather with aberrations from the normal type. They are themselves necessary evils. Even in its broadest sense, that in which criticism aims to point out both merits and defects, it has never yet proved itself able in a crisis to prevent the deterioration of literature. It did not do so in the critical senile periods of Greek, Roman, and Hebrew literatures. We do not say that it may never be able in the future to do this; we hope, on the contrary, that it may. But we deal with facts.

Again, criticism and psychiatry have little in common. In spite of Max Nordau, we do not believe that the deteriorated art and literature of the present day are the products exclusively of hysterics, neurasthenics, and paranoiacs. The attempt to prove that they are is the most astounding solecism of the season. In this thesis Nordau shows plainly the tendency of the extremists of the cult of Lombroso. He seizes upon the stigmata of hysteria and degeneration, which he thinks he finds in every line of every rhapsody of every poor devil poet and novelist on the continent of Europe, and pieces them together in a sort of symptomatology in order to make a diagnosis. The effect is sometimes striking, occasionally even convincing, but too often highly absurd. In other words, Nordau attempts to write a critique in the likeness of a monograph on insanity; he borrows the terms of psychiatry for the delineation of the literary characteristics of contemporary poets; he builds up a symptomatology in verse, a prognosis on quotations, and a therapeutics of denunciation. He does all this without seeing a patient, but only by reading his books; and then he seriously (but we suspect with his tongue in his cheek) dedicates his book to Lombroso and launches it upon the world. It does not seem to have occurred to him that he was simply following the method of Zola (whom he abhors), who claims that he consults the scientists in the preparation of his fictions.

The more conspicuous degenerates, whose cases are reported by Nordau, are Ruskin, Rossetti, Swinburne, Verlaine, Walt Whitman, Wagner, Tolstoi, and Zola—not to speak of one Nietzsche, whom nobody in this country knows, or is likely ever to know, much about, and who seems, from extracts supplied by Nordau, to have been a real lunatic. We by no means concede that all of these men are to be considered as abnormal. In fact, some of them are far above the average man; but taking Nordau's idea, the underlying defect of these "perverts," as nearly as we can put it in a single phrase for such diverse individualities, is that in one or more ways they represent the nineteenth century's disregard for and departure from all or many of the fixed rules and true standards which the history of mankind has established after infinite pains and progressive evolution as the normal types in art, literature, and philosophy. They are *atypical*. They have come, all of them, hailing the dawn of a new era; they affect to represent not a renaissance, but a new creation. They aim to bring forth new forms, because, as they claim, the old classic forms are dead. As a consequence we have the moonshine of Rossetti and the Preraphaelites, the verbiage of Swinburne, the rhetoric of John Ruskin, the grotesque lines of Whitman, the unceasing din of Wagner, the theosophy of Tolstoi, and "ibsenities" from Scandinavia, and obscenities from Paris. These, and their hosts of imitators, plagiarists, and claqueurs, fill the world with their noise, and constitute the culture of the end of the nineteenth century. They are all that we have—except the newspapers and the magazines, and the commonplaces of Mr. Howells!

This is all bad enough, but we do not see in it (except, perhaps, here and there in the utterances of some poor fool like Maeterlinck, who is by some chance still out of the asylum) the symptoms of the madness, and hysteria, and degeneracy of the whole generation. We do not believe, for that matter, in the madness of a whole generation. It requires a graduate of the school of Lombroso to see *that*. Science or history has never demonstrated such an instance yet in any period. We do not confuse literary deterioration with somatic alterations in the brain-cells. We adjudge, moreover, that it is an anomaly for a critic to mistake himself for an alienist when he analyzes a verse or annihilates a novel. Insanity is one thing; bad letters is another. Insanity can be measured by statistics; poor literature only with a yardstick. The poet, whose eye rolled in a fine frenzy, was not, we assure Nordau, ready to be certified.

Hence, we assume that Nordau has not yet attained that mastery of himself that would make him either a sound scientist or a safe critic. He has confused two fields of intellectual activity—*i. e.*, psychiatry and criticism—which have but little in

common and which are not subject to the same methods of treatment. Therefore, he has himself departed from a normal type. In this he displays, as we have already intimated, the tendency of the extreme school of Lombroso. This school aims to establish upon scientific foundations the recognition of the *abnormal* man. It has, heretofore, confined itself mainly to the fields of criminology and psychiatry. It has remained for Nordau to attempt to carry its methods into the field of literary criticism. We doubt whether this attempt will gain permanent recognition.

We have, nevertheless, found much in Nordau that has impressed us deeply. He is better as a critic than as an alienist, and we wish sincerely that he had confined the exercise of his pre-eminent genius to the field in which it is fitted for its best endeavors, and had not made his incursions so boldly, even recklessly, into that of mental therapeutics. He recognizes more accurately than any observer with whom we are acquainted some of the radical defects in the spurious culture of the present day. This is an aberrant time and generation; wandering not so much from the technical standard of mental health as from the typical forms in art and letters, without which we believe there is no health in them. The old classic types are not lightly to be ignored. As Nature has laid down her archetypes (for instance, the vertebrate skeleton), which she modifies in countless ways but never abandons, so the unconscious energies and instinctive wisdom of mankind, in their laborious development, have evolved the invaluable archetypes of art and literature. To depart from them in the one case as in the other is not an evidence of health or originality, but is simply a departure from the norm. This fundamental truth, which underlies all true criticism, is, after all, the keynote to Nordau's book. If he had not attempted to demonstrate the forced analogies between literary deterioration and mental degeneration, we think that he would have produced a more symmetrical work. But in that case his work would not have been a true product of the close of the nineteenth century—because Nordau's book itself, as we have said, is somewhat *fin de siècle*.

INACCURACY IN SCIENTIFIC TERMS.

The July number of the *American Journal of Pharmacy* contains some strictures upon the carelessness with which medical writers use chemic terms, and the ignorance displayed concerning even the simpler data of chemistry. The criticism relates especially to a paper on "Calomel," read at the last meeting of the American Medical Association, and is justified not only by the quotations from the paper, but also by the ordinary course of medical literature. Much of this carelessness or ignorance arises from the indifference that medical students are disposed to show toward theoretic instruction, but much also arises from the great complexity of chemistry and its rapid expansion, so that it is difficult, even for professional chemists, to maintain a comprehensive knowledge of the subject. It is, however, to editors and secretaries that we should look for the correction of such errors. We cannot expect the mass of the medical profession to be experts in the use of the terminology of chemistry, physics, or biology, but medical journals and societies that pretend to exercise literary authority should regard supervision of the scientific terms as of equal importance with the supervision of the grammar. There is no more justification for the term "oxid of calomel"—which occurs in the report of the discussion of the paper in question—than for the phrase "healthy drink," which we notice in the *Journal of Pharmacy* on the page opposite to that on which the critical editorial appears.

It is just by preventing the slipshod use of words and by securing consistency in terminology that editors fulfil their highest and most important function. In conducting a scientific journal it is not expected that the editor will exercise a very strict control over the quality of contributions from the point of view of their literary style or probable popularity, as would be done by the editor of a newspaper or magazine. Almost any issue of a medical journal will show a collection of articles of very unequal merit and moment, but contributors should be expected to conform to certain standards of spelling and nomenclature, and it is the editor's duty to see that the standards are maintained.

Some months ago a prominent medical journal discussed editorially some statistics upon the use of well-known drugs, and referred to "iodide of potash." This expression is a common error among medical men, and when a chemist ventures to criticise it the reply generally is that nomenclature in chemistry changes so frequently that it is impossible for those who are not chemists to keep up with it. It is true that some changes have been made in chemic

terms since the system was founded, but apart from those that have been additive, that is, due to the expansion of the science, very few have been made, and these have been decidedly in the direction of simplicity and precision, qualities that should recommend them to all intelligent persons. Concerning such expressions as "iodide of potash," it may be said that they have not even antiquity in their favor. It is not likely that they were ever used by chemists. In the early part of this century—in Chemistry's "hot youth, when George III was king"—an erroneous view as to the nature of salts led to the use of such phrases as "hydriodate of potash," "muriate of potash," a terminology that survives, in permissible use, in "muriate of ammonia," but the phrase "iodide of potash" does not stand for any theory, past or present.

This question is one not merely of words or of defence of certain methods of spelling. Precision in scientific terms is the basis of precision in scientific ideas, and to this end minute accuracy in phraseology is essential. In a recent State examination the applicants were asked to describe the alkaloid "strychnia." It may be hypercritical to say that this word is obsolete, but, as a term for a substance designated by chemists by a slightly different name, the word *strychnia* was made current by the *Pharmacopœia*, but changed by the terminology of the *Pharmacopœia* of 1880 to *strychnina*, and careful writers will either use the strict chemic term *strychnin* or the approved pharmaceutic term *strychnina*. Similarly, another question asked at the same examination was, "How would you test for arsenic?" There may be some doubt as to what is here meant by arsenic. The term applies to both the free element and to one of its oxids, and the preferable test for one is not the preferable test for the other. Moreover, assuming, as is probable, that the common oxid is meant, the question may arise under what conditions is the test to be made? The recognition of this body in a sample of vermin-poison, for instance, would require a different method than would be used in detecting the same body in vomited matter or in the stomach.

EDITORIAL COMMENTS.

Vital Statistics.—The death-rate of Denver, Colorado, for the twelve months ending June 30, 1895, according to the report of the Denver City Bureau of Health, was 11.52 per 1000. This is a very low mortality, and, as the population on which the rate has been computed has been estimated from the Census of 1890, it is questionable if the figures are accurate.

The population of Denver in 1890 was 106,713. It is estimated for 1894 at 145,000, an increase in four years of 45 per cent. Chicago reckons its increase in the past four years at 55 per cent., while New York considers 22 per cent. a proper estimate, and Philadelphia is satisfied with 11 per cent. According to the estimated population Chicago has a death-rate of 15.24, the lowest of any city in the world with a population over 200,000.

The census of the United States and the police census are seldom accurate, and it does not require much change in the popuation to effect a decided change in the rate of deaths per 1000. In small towns the registry of births and deaths is usually faulty, and when Chicago annexed many of the surrounding suburbs it did not take into account the lax registration, while it did compute its death-rate on the total population.

The New England States have endeavored to establish a uniform system of vital statistics, and the secretaries of the Boards of Health of Maine, New Hampshire, Vermont, Massachusetts, Rhode Island, and Connecticut held a meeting last September at which it was decided to publish a summary of the vital statistics of these States. The first one (for the year 1892) has just been issued, and, while it is incomplete in many respects, it is the beginning of what we hope will be an international system of vital statistics. Only then will an accurate annual statement concerning the population, deaths, and births of the principal countries of the world be possible and forthcoming.

The New England summary will be published only every five years, and, unfortunately, will consider the statistics of a year, antedating the report three years. The summary contains numerous interesting features. We find that the number of births per thousand exceeds the number of deaths by five, whereas in European countries, with the exception of France and Ireland, 10 and 11 per 1000 is the average excess of births over deaths. These results, however, cannot be viewed too critically, as in many countries, and especially in America, the births are not registered with as great accuracy as the deaths.

In England the parish registry and in Germany the strict police census make the returns of births more certain and more reliable, but in our own large cities, and in the smaller towns where no health-boards exist, the number of births registered falls largely short of the actual number of children born. The death-rate for 1892 in the New England States was 19.9 per cent.; 19.71 per cent. of the deaths occurred in children under one year of age, while 1.35 per cent. were in persons between ninety and one-hundred years of age. Pulmonary tuberculosis caused 10 per cent. of the deaths, or 21.8 deaths among every 10,000 living persons. Diseases of the circulatory system caused 16.17 deaths in every 10,000 living, while pneumonia, bronchitis, and influenza combined were responsible for 16 per cent. of all the deaths, or 34.7 in every 10,000 of the population.

The data on marriages and divorces are valuable from a sociologic point of view, while the study of the statistics of cities, as compared with that of the statistics of the rural districts, is a feature not yet well investigated. If the rural towns have a death-rate of 18.72 per 1000, and

the cities one of 21.01, then every additional suburban district that a city acquires will tend to diminish its general death-rate.

Vital statistics form the basis of public hygiene. Without accurate reports we can have no idea of the influence of sanitary measures on the social health or of the results of unhygienic conditions. Although after we have the figures we may juggle with them to suit our particular theory, nevertheless the figures themselves are not to blame, and are the bricks with which we must build if we would build at all. How necessary is it, therefore, that every scientific, and even unscientific, medical man should accurately make the returns required by a city's bureau of statistics, and where no such bureau exists should see to it that one is established.

Enforcing the Law.—Our most esteemed contemporary, the *Philadelphia Polyclinic*, asks whether it is or is not worth while, if we have a Code, to compel conformity with its requirements upon the part of those who need such compulsion? The question answers itself; of course it is "worth while," and it should be done, but how is the compulsion to be brought about? If our friend will tell us how it is to be done, we shall gladly cry, Bravo and amen! The machinery does not exist—or, if you will, the machinery exists, but there is no steam in the boiler. Censors do not act; it is impossible to incense them. Bring to their notice the most flagrant violation of the Code (the organic law of the Society) on the part of one of their members, and you are advised that you would "better not raise a fuss." In democracies how can a law be executed that the majority of the subjects do not wish executed? Surely there are no worse code-smashers than some of the highest executive officers of some large medical societies having the Code as their accepted law. Therefore it strikes us that we *did* answer "the main point of the objection" made by our correspondent in our issue of July 20th.

Suppose "penalties are attached," who is to execute the penalties? Penalties are at present attached—the only possible one that is desired or desirable—the penalty of expulsion of the violator from societary membership. But whoever heard of the expulsion of any one of the thousand code-smashers and law-breakers that infest and even officer many medical societies? A few expulsions on the part of every society in the land would at once make a revolution in professional opinion and practice exactly like that effected by the police-commissioners of New York City. But to put this steam in the boiler, thus to give vitality and force to the dead laws, constitutions, and rules of medical societies, their members and censors and officers must desire and resolve to execute the laws. At present they give no evidence that they so desire and so resolve. Ever and again down comes the question to one of personality. These men must be differently minded men. All reform, all progress begins and ends in individual character, in ideas and sentiments of personal dignity and honor, in the silent resolve to do one's own duty, to be true, and so far as possible to realize in daily life these ideals and sentiments. No one can doubt that such legacies of preceding generations, as codes, Bibles, laws, customs, and institutions—the concrete incarnations and products of human experience—are of great value in shaping present conduct and present growth. But we are all democrats and the animus of democracy—of much democracy—is to fling to the dogs the crystallized experience of the past, and to relearn it by other experience. And that is the weakness of the democratic idea.

It is characteristic of the upstart impertinence of conceited jackanapes to think they are wiser than their fathers or than all their fathers combined, and with headstrong folly to deny the validity of past experience. Perhaps they will one of these days come back from their codelessness, breedinglessness, godlessness, and "riotous living," in a very meek attitude of mind, having learned that their ancestors were not such fools as the descendants have just proved themselves to be. But as to penalty, the only one is exclusion from societies, and at present it seems that this cannot be effected. A man will hardly vote to exclude himself—a man cannot banish his own shadow. About all we can for the time expect is that we may keep the law standing (it is, even dead, an instigator of the tribute of the hyprocrisy that vice pays to virtue), and one day the anarchists who agreed to smash codes and remake the universe will learn that among themselves and for their own self-protection they have to re-enact the identical laws they smashed in starting their madcap civilization. In the meantime, whether to prevent the abrogation of the Code or to carry out its provisions energetically will depend solely upon the personal character of individual members of the profession and of individual societies. To form right character is the work of each and all of us and of an indefinite future.

Antivivisection for Children.—It strikes us that of all men physicians should be foremost and most emphatic in their denunciation of vivisection in the public schools or in any schools except those for adults and those especially devoting themselves to medical or biologic science. The matter would hardly seem to need argumentation. Every right-minded person must know, and doubtless must painfully remember in his own case, how callous children are to suffering and even how verily diabolic they often are as tormentors of animals over which they have power. It would also seem perfectly plain that the practice of vivisection before or by such highly imitative beings would have one certain effect: to increase enormously the already thoughtlessly or consciously cruel tendencies of their natures. "Appetite grows by eating." In medieval times the great gala days were the days of *auto da fé*. Gay cavaliers and gay ladies flirted and laughed for hours before men slowly being burned to death. They were no more intentionally or really cruel than boys to-day who pour coal-oil over dogs and burn them to death.

Would vivisection in public schools have other effects more than compensatory for the evil? Clearly and decidedly not. In the first place, dissection and anatomy and the advanced physiology to be gained by vivisection are not fit studies for the child-mind, but are plainly adapted and adaptable only to a maturer age, and for those preparing to become physicians or specialists. The child-mind is not by its very nature analytic, and any attempt to force it into analytic studies before a riper season is squarely contrary to pedagogic science. It is not only against the child's nature and bound to prove unsuccessful, but, if possible, it would not be desirable. We need to teach the young mind the beauty of life, not

the analysis of death. In educational methods we are at last fairly emerging from the barbarism of the study of dead things by dead methods and by dead-alive teachers. Do not let us encourage any such reversion to the barbarism of medievalism, as turning the kindergarten, that divine promise of a future civilization, into a miniature dissection-room or laboratory for experimental physiology. Moreover, in the interests of physiology, of medicine, and of science itself, we should protest against such physiology as would be taught in the public schools by the present-day (or promised) public school-teacher. *Gott bewahr!*

We said that physicians should be particularly enthusiastic in opposing the practice of vivisection-experiments before children. And why? First, because physicians generally are the kindest-hearted of men; the great body of the profession detest the excesses of the vivisection-mania that have at times, and sometimes justly, been charged to medical science. The great body of the profession are by no means anti-antivivisectionists, and are little inclined to clap the capers of such extremists, because these do harm to the nobler cause of scientific vivisection for laudable purposes by laudable methods—a cause that every genuinely scientific man has at heart. And precisely because he has this cause at heart, he is not minded to kick up a fuss with a lot of foolish old women and reverend sentimentalists every time a cat jumps over a wall. One who is really interested in science does not try to arouse antipathy to the profession of medicine by vivisection-somersaults in the market-place. He attempts to teach kindly even the worst sentimentalists, and to instruct them patiently in the ways and purposes of true science. We have already had entirely too much cantankerous opposition, extremism, and prejudice aroused in the popular mind against us and against vivisection by some of our equally silly extremism.

The Nurse, the Nostrum-advertiser, and the Puzzle-bribe.—We have long wondered why it was that the sympathy of the nurse had not been exploited by the lynx-eyed professional advertiser. Surely her experience with the sick should have made her an expert judge of the value and physiologic action of drugs, and her testimonials should alternate in all circulars hereafter with those of the gullible D.D.'s and the purchasable M.D.'s. Perhaps the nurses during the long "night-watches," viewing the worthlessness of the treatment of the regular physician, might by the glowing puffs and testimonials be prevailed upon to give the dying patient antisicknia or contramorbin, and thus save his life, much to the glory of the scientific layman too "broad-minded" to divulge his precious secret. At last one of the broad-gauged gentlemen has struck the vein, the geologic one, the gold-stratum, and sends his circular to all the nurses. It begins thus:

"In your vocation as nurse you, no doubt, often are in want of some little thing to entertain either yourself or your patient. At times it is difficult to keep awake without something to engage one's thoughts, especially during the night-watches. We have obtained several puzzles that have proved useful in entertaining people at social gatherings and at odd moments. We believe that you could make good use of them in the homes you visit.

"We shall be pleased to send you two of our best puzzles if you will kindly acknowledge having received the trial box of ——— we have mailed to you and will try the remedy, in case you are subject to headache, or give it to some one who will try it. One of the puzzles referred to is almost infinite in its possible combinations, and does not lose its interest after having been solved one way.

"The merits of ——— have been acknowledged by scores of physicians. One of them recently said that he used ——— with great benefit in the treatment of a lady who could not take one of the safest coal-tar products because it depressed the action of the heart. ——— afforded the desired relief without causing any depression. In view of your calling and probable familiarity with the remedies of this class, we believe you will appreciate and esteem ———."

The U. S. Marine-hospital Service.—The report of the Supervising Surgeon-General of the Marine-hospital Service of the United States for the year ending June 30, 1893, in two volumes, recently issued, contains some interesting statistics relating to the diseases that affect the seamen under the charge of the department. The service is divided into geographic districts. There were treated in hospitals under the supervision of the medical officers 14,857 patients. Among these there were 487 deaths (3.21 per cent.). The average number of days' relief given each patient was 26.5. There were treated in the dispensary and office 38,460 cases

As bearing upon the frequency of gonorrhea among this and similar classes, it appears that of 53,317 patients who applied for medical relief 4600 were affected with gonorrhea, 9 per cent. of the whole number. Forty-two-hundred-and-sixty-seven had secondary syphilis and 1805 were treated for ulcer of the penis. Only 250 of the patients were treated for valvular disease of the heart.

Of the 3070 applicants for admission into the marine service as seamen, pilots, and officers, 121 were rejected for physical disability. There were 43 rejections for color-blindness; only 7 for valvular disease of the heart; 4 for pulmonary tuberculosis; and 23 for genito-urinary troubles; gonorrhea causing 4 rejections and ulcer of the penis 8.

The frequent presence of venereal disease among sailors has always been recognized, but that so large a percentage should be afflicted would seem to demand some measures of prevention or suppression. If gonorrhea in the applicant is sufficient cause for rejection, it would seem that repeated attacks of this disease might warrant expulsion from the service.

The evil effects of gonorrhea and its transmissibility should serve to bring about some restrictive laws, and punishment of the affected individual would probably do more good than the licensing of prostitution with its supposed hygienic regulations.

Of 35 candidates who presented themselves for examination for admission into the medical corps, only 3 received the required grade-mark of 80 per cent.

Sunlight as a Germicide.—That certain members of the human species "love darkness rather than light" has long been well known, but that this same preference extended into the plant-world is a more recent discovery. The saprophytic and parasitic bacteria cannot bear sunlight. Like all other evil-doers, they are sneaks and cowards. Even such a ferocious and merciless cut-

throat as the *Bacillus anthracis*, who can invade almost any organic tissue, cannot manage to flourish in the sunlight. Some recent experiments of Marshall Ward's have shown this very prettily. A pure culture of the bacillus was grown upon a plate of glass to which sunlight was admitted through the openings of a stencil-letter, and after twenty-four hours of incubation the shape of the letter was clearly outlined upon the plate. Upon the parts to which the light had access, all growth was stopped, except that after several days' incubation a few feeble colonies appeared scattered over the illuminated area. The light was then decomposed and other experiments tried, which resulted in showing that the red, orange, yellow, and true-green rays exerted very little bactericidal effect, which was produced almost entirely by the blue and blue-violet rays. This revelation will, no doubt, delight our "blue-glass" friends. The same effect has been known for some time to be produced upon other pathogenic germs, notably the typhoid and Klebs-Loeffler bacilli, by sunlight. Indeed, it has been suggested that these organisms might be attenuated for inoculation-purposes by longer or shorter exposures. All of this simply confirms the oft-enunciated conviction that sunshine is "the one thing needful," the true "greatest thing in the world." We should insist that every living-room be sunlit, and "*Licht, mehr Licht*," physical as well as mental, should be our constant cry.

—

The Index Medicus.—There seems reason to hope that the *Index Medicus* will be revived, but whether it will or not will depend upon the response of the medical profession in the present emergency. In a letter to the Resident Librarian of the Royal Medical and Chirurgical Society of London, on the subject of the publication of the *Index*, Dr. John S. Billings states that "the cost of producing the work is about $4800 per annum, but as the amount of medical literature is increasing it is safest to put it at $5000. It is proposed to try to get 200 subscriptions at $25 each." It is estimated that 120 subscriptions can be obtained in the United States; sixty in Great Britain, and twenty in France and Germany. "Only 202 copies will be printed, no exchanges will be made, and there will be no advertisements. The subscriptions are to be paid in advance for one year to either of the undersigned (Dr. John S. Billings and Dr. Robert Fletcher). When 200 subscriptions have been received the list will close and the work will commence. It is thought that the first number may appear in November. If by December 1st the 200 subscriptions have not been obtained, the money then received will be returned to the subscribers, and the attempt will be abandoned." Surely, there should be no difficulty in putting into effect this proposition. Having been made to realize what the loss of the *Index* to scientific medicine would mean the response should be immediate and unequivocal.

—

Dr. Roberts Bartholow.—As there have appeared recently in several journals utterly unfounded references to the ill-health of this distinguished clinician and therapeutist, we take occasion to repeat the statement already made in these columns that Dr. Bartholow is in excellent health and is engaged in his professional duties with his accustomed zeal and vigor.

CORRESPONDENCE.

LONDON LETTER.

The Registration of Midwives—Honors for the Medical Profession—The Queen and Her Resident Physicians—The Death of Huxley—The Late D. Wilhelm Meyer—The Testimonial to W. G. Grace—Scientific Progress.

The question that excites most interest in the medical profession here at present is the proposed registration of midwives. A bill making such registration compulsory has recently been exercising the august intellects of hereditary legislators in the House of Lords, and seemed in a fair way to become a law, when the killing frost of the dissolution nipped its root. As things now are any woman can call herself a midwife in this country and play the part of Lucina among her sisters in their hour of travail without any guarantee that she knows more of the obstetric art than "My Uncle Toby." The results of this state of things among the poor may easily be imagined. To say nothing of frightful injuries caused by their active or passive ignorance, the dirty and often drunken women who act as midwives are always likely instruments for the distribution of puerperal sepsis. Darker things, such as abortion-mongering and child-murder, are hinted at. That such things are done is certain, but our midwives as a class, fortunately, have too little knowledge for the safe practice of crime. The fact that the English law does not require that still-births should be registered, however, makes it easy for unscrupulous persons to assist Nature in the elimination of superfluous infants.

The London Obstetrical Society has for years striven to the best of its power to remedy the evils that have been referred to by holding examinations of women wishing to act as midwives and granting certificates to those coming up to the required standard of knowledge. The movement for the registration of midwives, which is intended to be a further step in the direction of securing poor women against incompetent midwives, has the active support of the President of the Obstetrical Society, Dr. Champneys, of Sir John Williams, a past President and the leader of the obstetric branch of the medical profession in this country, and of the majority of English obstetricians. There is considerable opposition to it, however, in the body of the profession, as is proved by the fact that many branches of the British Medical Association have passed resolutions strongly disapproving of the proposed measure. It would perhaps be unjust to say that this opposition is prompted solely by sordid motives, but it is impossible to deny that the feeling of the profession in the matter has been fanned from one of "benevolent neutrality" to more or less active hostility by the persevering denunciations of a band of agitators (in which the Hibernian element is conspicuous), who make no secret of their determination to put every obstacle in the way of the betterment of midwives, which they profess to regard as the creation of a new order of qualified medical practitioners. To speak plainly, they are afraid of the competition of these women, and their objections to the registration of midwives resolve themselves into the *argumentum ad crumenam*. This attitude on the part of a profession, which is nothing if not philanthropic, is the reverse of edifying.

It is some comfort to those among us who have the dignity of their calling at heart that the General Medical Council, which not long ago allowed itself to be misled by the clamor of a small but noisy faction into condemning the certificates issued to midwives by the London Obstetrical Society, has now (though somewhat grudgingly) approved of the principle of the bill. For the present, of course, the registration of midwives is not, in Gladstone's phrase, "within the sphere of practical politics," and the new government will for a time have its hands full of matters more important from a political point of view. The omens are, however, more favorable to the passing of such a measure than they were when the star of Lord Rosebery was in the ascendant. The Tories have not so many faddists in their ranks as the Liberals, and in matters concerning public health they have much more legislative backbone than their rivals.

When a government goes out in this country it throws a handful of titles and decorations among its supporters, as a parting guest "tips" the servants of the house he is leaving. The medical profession, which as a body has little or no political influence, does not usually come in for recognition on these occasions, but this time the "honor of Knighthood" has been conferred on two Dublin doctors, henceforth to be known as Sir Thornley Stoker and Sir Christopher Nixon. The distinction—such as it is—is no doubt intended as a sop to the political party (Home Rule) to which they belong, but both are of a professional standing that makes such an acknowledgment acceptable to their brethren. Sir Thornley Stoker is President of the Irish College of Surgeons, and is a brother of Mr. Bram Stoker, the *fidus Achates* of Henry Irving, and (if rumors lie not) the inspirer of that hirsute histrion's after-dinner eloquence and academic prolusions. Sir Christopher Nixon is equally eminent in the Irish Capital as a physician and as an amphitryon; in the words of an admiring compatriot, he is "a noice mahn and a noice-mannered mahn."

In connection with this subject of honors it may be mentioned that the Queen has "of her own mere motion" (as the royal style runs) made her resident physician, Dr. James Reid, a Knight Commander of the Most Honorable Order of the Bath. This may not sound a very exalted dignity to republican ears, but connoisseurs in such toys estimate the value of a decoration as bibliomaniacs do that of an old chap-book—by its rarity. From this point of view the cabalistic letters "K.C.B." appended to the name of a physician must be accounted very precious, for there are only four other members of the medical profession on the roll, viz.: Sir Henry Acland, Sir Rutherford Alcock, Sir William Flower, and Sir John Kirk. In none of these cases, however, has the honor been bestowed for purely professional distinction. Sir Henry Acland was for many years Regius Professor of Medicine in the University of Oxford, and took a prominent part in establishing the splendid museum of that ancient seat of learning. He is a type of the old stately race of academic dons, and a man of varied erudition, who is said by his friends to add some knowledge of medicine to his many intellectual accomplishments. Sir William Flower was for many years surgeon to the Middlesex Hospital, but it is as Director of the Natural History Museum that his title was given him. Sir Rutherford Alcock is one of the oldest members of the Royal College of Surgeons of England, but it was in the diplomatic service that he won his K.C.B. Sir John Kirk got his, not for medical work, but for his services as British Consul-General of Zanzibar.

One member of the medical profession, Sir William Jenner, holds the coveted distinction of Grand Cross of the Bath—that is to say, he is in the first class of that highly rarefied order among serene transparencies and other ethereal beings, but he is a man whom the Queen greatly delights to honor. Sir James Reid, who is forty-six years of age, is a Scotchman, a race that finds especial favor in her majesty's eyes. He was appointed to his present post in 1881, largely owing to the influence of the late John Brown, the Queen's highly privileged "gillie." He accompanies the Queen wherever she goes, and is always with the Court except for a fortnight in the spring and a week or two in the autumn, when he is allowed a brief holiday. Sir William Jenner, though he has retired from active practice, still exercises a general supervision over the Queen's health, and visits her once a fortnight when she is at Windsor or Balmoral.

Sir James Reid receives a very moderate salary, but he has a residence both in Buckingham Palace and at Windsor, and as matrimony is not among the privileges allowed him his expenses cannot be great. With all its apparent dignity, the position is not far removed from that of an upper servant, and the want of the ordinary stimuli to exertion must tend to make whatever stock of scientific knowledge one started with run to seed.

Sir James Reid's predecessor, Dr. Marshall, fell into a pitiable state of gibbering melancholia before he died, in consequence, it was believed, of the monotony and isolation, intellectual as well as social, of his life. He continued at his post for many years before it occurred to the Queen that he might possibly need a holiday. When the poor man did at last get his royal mistress' gracious consent to a brief respite from court-attendance, he was summoned back in a week or two because John Brown was indisposed. That autocrat of the backstairs would not trust his precious person in the hands of the late Dr. Wilson Fox, one of the first physicians of England, who, though intrusted by Sir William Jenner with the care of the sovereign's health, was not thought good enough for himself by her flunky. Dr. Marshall received a salary of £400 a year, and when after some fourteen years' faithful service it was raised to £500, he was given to understand that he should consider himself treated with especial liberality. When it was necessary to find a successor there were many candidates for the post, but when Sir William Jenner—of whom his worst enemy cannot say that he uses language to conceal his thought—had told them the plain, unvarnished truth about the appointment, how it was little better than living in a gilded prison; how the movements and actions of the unfortunate physician were hedged about with all sorts of vexatious restrictions; how he could go out of doors only when "Her Most Gracious" had gone for her daily drive; how his only society was gentlemen-in-waiting and maids of honor, fashionable fribbles and feeblings, whose minds were etiolated by the blighting air of a court, and who looked down upon him as an inferior; their vaulting ambition sought for something less prickly

than a crown to exercise itself upon. One man who was induced to make a trial of the post resigned it after three months, and, when he was asked to stay, is reported to have replied that he would not do so for £10,000 a year. It should, however, be stated that Sir James Reid is in a different position from his predecessor, for he has the care of the earthly tenement of the Queen herself, as well as that of the commoner clay of her household. It is whispered that until lately she has not been an easy patient to manage, having been all her life given to defying the elements, to the grievous discomfort and not infrequently to the bodily detriment of her attendants. At last, however, she is beginning to feel that cruel age hath clawed her in his clutch, and this makes her more docile to the advice of her physicians.

In Huxley the medical profession in this country has lost the man of whom it had most reason to be proud. One of those who stood by his bedside throughout his long illness has told me that the philosopher was greater in his death even than in his books, adding with the emphasis of heartfelt conviction: "He was a grand man." It was characteristic of him that he joked with his physicians and with those about him to the very last. On one occasion when a medical oracle from London was rather aggressively jocose, Huxley said afterward that he had felt bound to respond, but that the effort had been too much for him. This little story has a moral for those physicians who think the sick-room is a place for the display of cheap wit; what is fun to them may be death to the patient. In his younger days Huxley was an assistant surgeon in the Royal Navy; a position which corresponded to that of surgeon's mate, as described by Smollett, was obtained after an examination somewhat on the lines of that passed by Roderick Random. Huxley was not qualified in the technical sense till years after he had left the Navy. He became M.R.C.S. in 1862, probably as a necessary preliminary to his being appointed Hunterian Professor of Comparative Anatomy. Afterward he was elected to the Fellowship. As bearing on the question of professional titles it may interest American readers to know that on Huxley being asked by a correspondent what was the correct manner of addressing him, replied that his visiting cards had never borne any other designation than "Mr. T. H. Huxley;" he added, however, that he did not particularly object to be styled "Professor," but he could not stand "Doctor." Yet he might have used the latter prefix with perfect propriety in the later years of his life, for besides his degrees of LL.D. and D.C.L. from Edinburgh, Oxford, and Cambridge, he was honorary M.D. of Würzburg. He died, as he had lived, an agnostic (to give him the denomination which he himself invented to describe his own mental attitude), but in obedience, it is said, to a wish expressed on his deathbed he was buried with the rites of the Church of England, beside a son who died in childhood.

Dr. Hans Wilhelm Meyer, of Copenhagen, who recently died of typhoid fever in that sink of unsanitary iniquity, Venice, was one of the few enlargers of the empire of medicine who have seen their discovery accepted as part of established scientific truth in their lifetime. Yet it is little more than twenty-five years ago since he described adenoid vegetations of the nasopharynx, and it was a considerable time before the affection came to be recognized by the profession in this country. Ten or twelve years ago the leading physician in London stated in my hearing that he had never heard of it, and even among specialists a knowledge of the existence of such growths was by no means common property at that time. A well-known otologist who was present at an operation for adenoid vegetations maintained in the most positive manner that the tissue removed was nothing but mucous membrane, and pretty plainly hinted that the whole business was a fraud. Another leading otologist, after vehemently denying their existence for years, suddenly found salvation in a somewhat mysterious manner. His conversion was as complete and almost as rapid as that of St. Paul, for after sitting at the feet of a laryngologic Gamaliel for a very short time, he came forward as an apostle of his new faith, which he preached with all the zeal of a discoverer. Both these men were among the elect, as regards rank and file of the profession; of the men who have been in practice over fifteen years, probably a very large proportion would be found who if they have ever heard of adenoid vegetations at all believe that they are mere products of what Tyndall called "the scientific use of the imagination" by specialists. Meyer had the appearance of a dissenting minister from a rural district, and Morell Mackenzie, who was very proud of his own manipulative dexterity, said after meeting him that one could see he was not an operator. Whether he was an operator or not, Meyer has been the means of brightening innumerable lives that would otherwise have been dark and useless.

Probably in no country but England would it occur to anyone to get up a subscription for a healthy adult male because he could strike a leather ball with a piece of wood oftener than most other people. The so-called "national testimonial" to W. G. Grace is a striking proof of the amazing gravity with which Englishmen treat cricket. Grace is better known to his countrymen than any statesman or soldier, artist or author, preacher or teacher that England can boast of; in popularity he surpasses even Gladstone, whose skill in tongue-fence is akin to Grace's deftness with the bat. So great a hero in British eyes is the champion cricketer that the medical profession is proud to claim him as a member; the *Lancet* pretends to believe that his medical training has something to do with his athletic prowess, and the *British Medical Journal* has started a subscription-list of its own for him. Meanwhile many a deserving member of the profession may starve. *Quantum est in rebus inane!* As Grace plays cricket all the summer, and is largely engaged in other forms of sport during the winter, one wonders when he finds time to attend to his medical practice. He had a preternaturally long career as a student at St. Bartholomew's Hospital, and it used to be a stock joke among the examiners at the College of Surgeons when he had come to grief for the *nth* time to say: "Bowled again, Mr. Grace." It would have been more in accordance with the fitness of things if he had been a vet. instead of a doctor, for he has made a living much more out of "balls" than out of "pills."

In the way of additions to the sum of knowledge in medicine there is nothing of importance to chronicle. In his researches on immunization against snake-poison, which were introduced to the world with a flourish of journalistic trumpets, Professor Fraser, of Edin-

burgh, has trodden in the footsteps of Dr. Calmette, a well-known pupil of Pasteur's, who, after doing much to spread the light of science in the far East (he was head of a bacteriologic institute at Saigon, Cochin-China), is now director of the Pasteur Institute at Lille, France. Of progress in other directions there is for the moment no sign, but our workers are following Grant's advice and "pegging away." As regards the diphtheria-antitoxin in particular, the only thing resembling an official deliverance on the subject is a statement reported to have been made by Sir J. Russell Reynolds, President of the Royal College of Physicians of London, and also of the British Medical Association, to an enterprising reviewer, that if his wife or child had diphtheria he would use the remedy. But we are still waiting for the report of the Metropolitan Asylums Board on the results obtained in the hospitals under their management.

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.

Sixty-third Annual Meeting, held at London, July 30 and 31, August 1 and 2, 1895.

(Continued from page 167.)

SECOND DAY—JULY 31ST.

SIR WILLIAM BROADBENT delivered the Address in Medicine. His subject was

THE GROWTH OF THE ART AND SCIENCE OF MEDICINE.

The words "art" and "science" were used in this order advisedly, for the art of healing is one of the primary needs of social organization, however rudimentary, and preceded by many ages the development of anything that could be called a science of medicine. So far, moreover, the art of healing has always been in advance of science, firmer in its basis and more secure in its principles, and, even when medicine as a science has realized our highest aspirations, the end and aim will be art—that is, skill in the recognition and treatment of disease. At the same time it is true that until science began to throw light on its path the art of healing struggled blindly on its way, and its advances were intermittent and slow, with long intervals in which there were stagnation and retrogression. All true progress in medicine has consisted in the application of the results of scientific investigation to the facts of observation.

At whatever period of the world's history and at whatever stage of civilization we may contemplate the physician engaged in combating disease, there will be recognizable three distinct factors in his work—his power of identifying disease, the remedies at his command, and the ideas by which he is guided in the employment of these remedies.

The first rough and imperfect identification of the more conspicuous forms of disease was scarcely worthy of the name of diagnosis. Anatomy, which is essential to the localization of morbid conditions, was scarcely known; no shadow of comprehension of physiologic or pathologic processes entered into the conception—it was simply the attaching of a name to an assemblage of symptoms, the course of which, however, was watched with great sagacity.

How remedies were first discovered and how the properties and uses of so many of them as were handed down from remote antiquity were known is matter for amazement. Animals are credited with instincts that direct them to the consumption of certain herbs or mineral substances when their health is deranged; the instincts of primitive man also must have applied to remedies as well as to food, and experience of their effects must have been accumulated and transmitted, embodied frequently in legend or superstition, as part of tribal knowledge.

Of the infancy of medicine, properly speaking, we know nothing. Individual acts of healing are related in the Old Testament, and the treatment of wounds is described by Homer; the Chinese from remote antiquity had a system of medicine, and medicine has a place in the *Vedas;* but in the works of Hippocrates, the earliest medical literature that has come down to us, we are at once introduced to the theory and practice of the art of healing at a considerably advanced stage of development. Already there were rival schools of thought and treatment, and disease was discussed with extraordinary acumen from opposite points of view both as regarded its nature and phenomena.

Bleeding was in every-day use, not by any means as a routine fashion, but with judgment; cupping also was practised. The virtues of opium were known, and purgatives of various kinds, chiefly irritating and violent, and emetics were familiar remedies; enemata and suppositories and pessaries were employed, and fomentations and poultices in great variety were applied.

Hippocrates, whose writings embody all our knowledge of ancient medicine, was born about 460 B.C. He was a contemporary of Socrates, Euripides, and Aristophanes, and was a worthy representative of medicine at that brilliant period of Greek literature and intellect called the age of Pericles.

It is true that his knowledge of anatomy was rudimentary, and that his physiologic ideas were totally wrong, but he has left of himself the picture of a sagacious observer and wise physician. He was the inheritor of the knowledge and traditions of the school of Cos, and another source of information by which he had profited was the training-establishments of athletes, where the influence of diet, gymnastics, and baths on health and vigor was carefully watched. His attitude of mind was toward the study of disease as such, rather than the differentiation of distinct diseases. Refinement in this latter direction had obviously been carried much too far by the school of Cnidos, which he criticised and opposed, where symptoms were looked upon as separate morbid entities.

His distinguishing merit, however, was that he was guided by observation and not by theory. Hippocrates could not, any more than his contemporaries or successors, or than we ourselves, escape the dominion of theory; but his theories were generalizations from observed facts, and not deductions from preconceived ideas or so-called first principles.

The doctrine with which his name is associated, that of the coction of humors and of critical days, for example, is essentially a generalization from the natural history of certain simple diseases. The facts were essentially facts of the natural history of disease. The theory evolved as an explanation of the course of events and

applied in the elucidation of disease of which the processes were not patent on the surface, was that some one of the four humors, the due balance of which constituted health, had obtained predominance and set up disturbance, general or local; this was concocted or elaborated by the animal heat, increased for the purpose, and qualified by admixture of other humors, and so brought into a condition in which it could be expelled and got rid of.

Hippocrates, from this subordination of theory to observation, from his careful study of the causation of disease, not less than from the lofty sentiments and clear judgments contained in his writings, remains, and must ever remain, the model physician.

During the 500 years that separated Galen from Hippocrates the center of gravity of the civilized world had shifted. Greece, shattered by conflict between its different States, had succumbed to Macedonia. Alexander had conquered Asia and then died. On the ruins of his empire Rome had gradually risen, and when Galen lived had extended her rule over Greece, Asia Minor, Egypt, and the southern littoral of the Mediterranean as well as over Gaul, Spain, and Britain. There had been time, however, for the development of a high degree of intellectual activity and literary culture under the Ptolemies in Egypt, and Alexandria had become a great center of learning. Here marked advances were made in anatomy; dissection was practised on human bodies as well as on animals. Herophilus, between 305 and 280 B.C., left his name to the confluence of the sinuses of the dura mater; Erasistratus, a contemporary, recognized in a crude way the motor and sensory functions of the nerves; Chrysermes, 240 B.C., wrote on the pulse, as did also Heraclides, 230 B.C.

Medical writings date from Alexandria as late as 170 A.D., but the school had long lost its authority, and Rome henceforth attracts the highest medical talent. The physicians who first made a name in Rome are Greeks—Asclepiades, the friend of Cicero, and Galen himself. Celsus, however, who comes between the two, writes in Latin.

Galen, who was born at Pergamos, A.D. 130, dominated medical thought for 1500 years, and if it was inevitable that authority should exercise such undisputed sway for so long a period it was perhaps fortunate that it derived from Galen. He was in spirit a follower of Hippocrates, and the basis of his ideas on disease and its treatment was observation. His keen and active intellect and fertile imagination, it is true, led him to theorize on every conceivable subject; but the impression left as to his character by reading his numerous works is that of an acute observer, of remarkable ingenuity and profound judgment, and excellent common sense.

He dissected diligently and thoroughly, but mainly monkeys rather than the human subject. Taking this into consideration, his writings on anatomy were wonderfully complete and exact. They held sway until the time of Vesalius. He finds the most ingenious reasons, often far-fetched and preposterous, for the form, consistence, and relations of all the various organs.

In respect of anatomy, his knowledge was incomparably superior to that of Hippocrates. He experimented on the spinal cord and on the nerves, and knew that they subserved motion and sensation—knew even that there were motor and sensory nerves distributed to the muscles and skin respectively, discovered the part taken by the recurrent laryngeal nerve in phonation, and, although his physiology is chiefly represented by fanciful teleologic explanations of the uses of the different parts and organs, he made noteworthy additions to the knowledge of functions.

Apparently Galen was the first to establish the fact that the kidneys secreted the urine, and that it was conveyed by the ureters to the bladder. At any rate, this was disputed in his time, the objection being that the urine could not be forced back through the ureters, and could not, therefore, have entered by these canals. The bladder was supposed to attract the urine. He demonstrated it by tying the ureters; and in the course of his experiment he almost stumbles on the discovery of the circulation, for he maintains that blood is carried by the renal arteries to the kidneys in order that its watery part may be filtered off. The traditional ideas as to the origin of the veins and of the flux and reflux of the blood in them, however, blinded him to this and other evidence, and he believed that the arteries contained air, though he maintained that they also contained blood.

A frequent reproach brought against Galen is that he spoke of the interventricular septum as perforated, so as to allow the passage of air between the two ventricles, against the evidence of his senses; but an excuse can be found for him in the fact that invisible communications had always been supposed to exist between the trachea and the arteries, by which air passed from one to the other. He can only have meant similar invisible perforations, the orifices of which he would think he saw in the depressions which the walls of the ventricles present.

Galen wrote more than a hundred treatises on various subjects, including six on the pulse, and, while giving extravagant descriptions and making fanciful comparisons, he pointed out distinctions and characters that have been verified by the sphygmograph.

His treatise on local affections is remarkably true to Nature, and no more impressive lesson on the value of observation, even when unaided by science and experiment, can be afforded than by realizing how fresh and vivid and modern his descriptions of diseases and symptoms sound. His diagnosis, for example, between hematemesis and hemoptysis and other forms and causes of blood-spitting leaves little to be desired.

Materia medica was always too multifarious, even in the earliest times, and that of Celsus and Galen was much more varied than that of Hippocrates. Theriaca, so named from containing viper's flesh, was the subject of a work by Galen. It was a complicated opiate electuary containing about 63 ingredients, among which, besides poppy-juice and the vipers, were pepper, rose-leaves, iris, licorice, cinnamon, nardus, cassia, crocus, frankincense, balsam, gum, fennel, cardamom. It is said to have been employed for 2000 years. Aloes, in Galen's hands, had largely taken the place of the irritating purgatives, such as hellebore and spurge, previously employed. Dioscorides, who wrote in the first or second century, describes more than 2000 substances, chiefly vegetable. It may be remembered that an attempt was made only last year to invalidate the patent for lanolin on the strength of a process for obtaining fatty matter from wool, given by Dioscorides.

The doctrine specially associated with the name of Galen is the humoral pathology accepted by him from Hippocrates, and developed. The humors are phlegm, blood, yellow bile, and black bile; and all diseases arise either from a change in the quality of these humors, or from a predominance of one or other of them, or a flux of some particular humor to a given part. But, like Hippocrates, Galen is first of all an observer, and his theories, faulty as they may be, are generalizations from observations, and not deductions from *a priori* assumptions as to the nature of things.

Both Hippocrates and Galen rejected the doctrine of the sect of empirics, who declared that experience alone, without reasoning as to the nature or relations of observed phenomena, and without reference to causation, or to the influence of climate, season, age, sex, character of constitution, or mode of life, was the only safe guide in the treatment of disease.

Hippocrates still more emphatically rejected the pseudo-philosophic deduction of rules of treatment from the abstract qualities, hot and cold, dry and moist, acrid and sweet; and Galen in his turn rebutted the methodic doctrine of Asclepiades and Themison, which he found prevailing in Rome, and according to which all diseases were referred to constriction and relaxation, and treatment consisted in relaxing and astringing.

A high standard of medical literature is maintained by Oribasius, the friend of Julian, from 350 to 400, by Aetius, who wrote near the end of the fifth century; Alexander, a little later in the reign of Justinian; and Paulus, who lived about 620; and improvements in practice can be traced during this period.

Alexander treated gout with purgatives, in which a kind of colchicum was a constituent. Paulus first described the aperient action of rhubarb, and extolled steel in scirrhus of the spleen.

After this there is a long gap in the history of medicine and of the liberal arts generally, but this is not to be wondered at. The Roman system of civilization was gradually broken up, and its warring fragments were shaped by geographic and racial conditions into States out of which modern Europe has grown.

The seat of Government was shifted from Rome to Constantinople in 330. Rome was sacked in 546 and 549; later the Church established its dominion over the ruins of the ancient city.

As countries and governments were organized and delivered from the pressure of constant war, universities were founded. At Salernum there were already professors of physic in the middle of the seventh century. Charlemagne founded a college here in 802, and the Schola Salernitana was dedicated to Duke Robert of Normandy, son of William the Conqueror. The Universities of Bologna and Paris almost rival in antiquity that of Salernum. Thus in these dark ages the revival of learning and the *renaissance* of art were being prepared.

Names that have remained famous began again to appear in the ninth century. The followers of Mohamed in the course of their conquests found at Alexandria the works of Hippocrates, Galen, and other early medical writers. These they translated into Arabic, and upon them was based the medical learning for which Arabian physicians became renowned. With the Moorish conquest of Spain, and the extraordinary culture and civilization developed by the invaders, the writings of Hippocrates, Galen, and the best Greek physicians, which had almost been lost sight of, came back to Europe with practical additions and modifications of great interest. Venesection was employed with greater moderation, and milder purgatives were substituted for hellebore and the like.

Rhazes, from 852 to 932 A.D., besides reproducing the most important works of Hippocrates and Galen, gave the first account of smallpox, which, like the plague and cholera, came to us from the East, where he had seen it before the Saracens brought it into Europe in the course of their invasion. His description of the disease served for 500 years, and it is perhaps worthy of remark that he compares it to a ferment in the blood, like must. He is said to have been the first to employ chemic as distinguished from Galenic remedies.

Avenzoar speaks of adherent pericardium and mediastinal abscess, and employed nutrient enemata. Albucasis appears to have been very enterprising as a surgeon. It was only at the end of the fifteenth century that, in the general revival of learning, Greek medical literature displaced the Arabian writers, and again resumed its authority.

While there is evidence that clinical medicine was seriously cultivated, such events as the visitation of the plague in 1348, which carried off one-fourth of the population of Europe, and modified profoundly social history, or the successive epidemics of the sweating-sickness, which specially affected England from 1485 to 1529, left no mark on the history of therapeutics. Syphilis, which first became prevalent and virulent in 1494, afforded better opportunities for the trial of remedies. Guaiacum obtained a reputation as a specific for this disease, which we do not now understand; but it was seen before long that mercury, which was employed in the form of inunction, was the real remedy. John of Vigo was the first to recommend mercurial inunction, but Carpus previously employed it as a secret remedy, and amassed a large fortune thereby. Fumigations were also practised. The effects were attributed to the carrying off of humor by the salivation that was produced. The introduction of mercury was an important addition to the materia medica.

Already in the fourteenth century *post-mortem* examinations and dissections of the human body were made. The imagination was stimulated and a material impulse was given to the energies and ambitions by the discovery of America in the fifteenth century, and the invention of printing in 1462 made general intellectual culture possible. An evidence of the revival of interest in medicine was that the practice of medicine, which had drifted into the hands of monks and priests, was reclaimed. Linacre in England took the licensing to practise out of the hands of the bishops, and founded the Royal College of Physicians in 1518.

The prodigious mental activity of the sixteeenth century took in medical matters the form of eager and close study of human anatomy. Vesalius challenged the accuracy of Galen, and was hauled before the Inquisition for his pains. Other names which mark this epoch and which have been left imprinted on some part of the human frame are Fabricius, Eustachius, Fallopius, Ingrassius, Colombus, Arantius, Varolius, while Servetus, Colombus, and Cæsalpinus almost penetrated the secret

of the circulation. This great discovery, however, was reserved for Harvey, and the publication of the *De Motu Cordis* in 1628 constituted the most important epoch in the history of medical, and, indeed, of biologic science. But while vindicating his undoubted claims, we must not forget that he owed his early knowledge of the anatomy of the heart and vessels to Fabricius, and drew his inspiration from the teaching he found at Padua. There is no need for me to dwell on the importance of the discovery of the circulation. When completed by the demonstration of the capillaries by Malpighi and by the discovery of the lacteals already made by Aselli in 1622, and of the receptaculum chyli and thoracic duct by Pecquet in 1647, and of the lymphatics by Steno somewhat later, the foundation was laid for physiology and the first step taken toward a real comprehension of disease.

It was a long time, however, before the establishment of the circulation began to bear fruit. Indirectly, it is true, an end was made of various absurd discussions, as, for example, whether bleeding ought to be done on the same side as a pleurisy or on the opposite side, which was the subject of a formal enunciation by the University of Salamanca to be enforced by legal penalties, and minds were emancipated from the authority that had enslaved them for so many centuries. But the first conclusions drawn from the circulation of the blood and lymph were absurd if not mischievous; one kind of blood was supposed to be conveyed to the muscles, another to glands, and the nerves were supposed to convey nutriment to white fibrous tissues, and a century after Harvey there were physicians who sat to Le Sage for the portrait of Sangrado, which he drew in *Gil Blas*, and to Molière for the character of Diafoirus.

While Sydenham, who wrote between 1666 and 1680, and Boerhaave (1668-1738), the best and most representative physicians of their respective times, fully realized the fact of the circulation of the blood, it had exercised remarkably little influence on the theoretic views that they entertained with regard to disease, or on their practice.

Sydenham may be called the English Hippocrates. He was the last and best of the pure Hippocratic school, unless, indeed, we include Trousseau. He was, above all, a careful clinical observer. With regard to remedies the great acquisition of Sydenham's time was bark, which had been brought over from America by Jesuit missionaries about the middle of the seventeenth century. After accepting it cautiously, he employed it freely but judiciously, laying down rules which have been found useful ever since. Mercury was of course in common use, and antimony was an acquisition of which he thought highly. Epidemics he attributed to influences emanating from the earth, and he considered that different years and the various seasons impressed different characters upon the prevalent diseases, in which, in fact, he followed Hippocrates. Other diseases were due to vitiation of the blood; Nature was engaged in the expulsion of the peccant substances. It was the business of the physician to co-operate with Nature, and his art consisted in recognizing the indications presented by the symptoms and the direction in which he must act in order to aid in restoring the normal equilibrium.

Boerhaave, whose principal works date from the first years of the eighteenth century, was also a great physician, and exercised by his writings and through his enthusiastic follower and commentator, van Swieten, a powerful and lasting influence on medical thought in his day. He evidently had great experience, and was successful in practice. He had the great merit, too, of teaching at the bedside. He seems to have thought that with the discovery of the circulation and the advances in botany, chemistry, physics, mechanics, and clinical experience, medicine had in his day attained to certainty and almost perfection, but his theories were drawn largely from the assumptions and imaginations of the iatro-mechanic school.

Nothing could more confirm us in our respect for the genius of Hippocrates and the good sense of Galen than to attempt to follow the fanciful extravagances which from time to time partially displaced their humoral pathology, and have been known as the iatro-chemic and iatro-mathematic or mechanic theories. Every discovery in alchemy, as early attempts at chemistry were called, and every new development of mathematic or mechanic science, was in turn seized upon as affording the clue to the causation and treatment of disease. Even the circulation of the blood and the early knowledge of structural anatomy were turned to perverse theoretic use. Just as for the methodics in the time of Galen every disease was referred to constriction or relaxation of parts, and the remedy sought in relaxants or astringents, so at one time all diseases were ascribed to acidity or alkalinity of the humors or to fermentations; or again to obstruction of pores or minute vessels and inspissation of liquids. The contraction of muscles was due to a sudden swelling of their substance set up by the nervous juice or spirits conveyed by the nerves. Respiration was for the purpose of giving a due comminution to the blood by the movements of the lungs. Fever was explained by an acrid nervous juice, which excited the heart to more frequent and forcible action.

Later still the physiologic discoveries of Haller, the establishment of the principle of irritability as a property of living tissues, and the employment of the term "stimulus" led to another general theory of disease—the doctrine that fever and inflammation were the result of over-stimulation, which was attended by a return to extravagant and indiscriminate bleeding. From this there was the Brownonian reaction to the contra-stimulant doctrine, with equally indiscriminate, if not equally mischievous, administration of stimulants. Even the revelations of morbid anatomy and pathology were at first made the basis of a general doctrine relating to disease—the organicism of Broussais; everything was referred to gastro-intestinal inflammation, and again venesection was the universal remedy.

Harvey's great discovery remained comparatively barren until it was supplemented by Lavoisier's explanation of the process of respiration, and indeed almost until a further impulse was given to thought and experiment by a diagnosis of diseases of the heart by means of physical signs.

Then an important step was made in the elucidation of the mechanism of the circulation by the discovery of the vasomotor nerves, and the demonstration of the contraction and dilatation of the arterioles in obedience to stimulation of these nerves, by Claude Bernard.

Almost concurrently the regulatory apparatus of the heart's action through the vagus and sympathetic was

identified by the brothers Weber. These discoveries were followed out in detail by a multitude of experimenters, and the adjustment of the supply of blood to local demands for the purposes of nutrition, secretion, muscular action, and the response of the heart to the general requirements of the system, to excitement, emotion, exercise, are now thoroughly understood.

It is only comparatively recently that the blood-pressure in the arteries and veins, and in different parts of the arterial and venous system, first measured tentatively by Stephen Hales, has been experimentally investigated by the graphic method by Ludwig and his school and made available for clinical work through the sphygmograph by Marey and his followers.

The relative share of the heart and vessels in the production of variations in the blood-pressure was thus made clear, and then for the first time the complex and multitudinous indications afforded by the pulse could be understood.

At the same time that the lacteals and lymphatics were discovered, the structure of the glands was investigated by Glisson and Wharton, and the minute anatomy of the tissues generally was initiated by Malpighi, Ruysch, and Leeuwenhoek, who demonstrated the capillaries by injection and recognized the corpuscular elements of the blood by means of the first rude form of microscope.

The invention of the microscope opened another avenue to knowledge, and every improvement in this instrument and in the preparation of structures for examination has been followed by a further penetration into the secrets of organization and a better comprehension of function. Staining, for example, has not only facilitated the identification of different structures in their minutest ramifications and most intricate combinations, but has made it possible to distinguish between active protoplasm, in whatever form it may be found, and the material formed by it, and has revealed essential differences between cells otherwise apparently alike in all respects.

Schwann and Schleiden laid the foundation of histologic science by the discovery of cells as the structural unit, and when the knowledge of minute anatomy had reached a certain point the results were systematized by Bichat, who by his general anatomy prepared the way for the cellular pathology of Virchow.

Side by side with advancing knowledge of structure has come increasing comprehension of function. Physiology from first to last is based on experiment. It was by experiment that Galen proved that the kidneys secreted and the bladder retained the urine, and learnt the motor and sensory functions of nerves, and that Bell, again, nearly seventeen-hundred years later, discovered that the posterior nerve-roots were sensory and the anterior roots motor. It was, of course, by experiment that the circulation of the blood was established. The advances made by Haller (1708–77), again, in the elucidation of vital action were based on experiment. It was not, however, till the example was set by Magendie that experiment was systematically employed in the investigation of all the functions. He was followed by Claude Bernard, to whom we owe our knowledge of the vasomotor apparatus and its influence on secretion and nutrition, and with whose name is associated the glycogenic function of the liver, which has been rudely questioned if not overthrown by Pavy; by Ludwig, who elucidated the dynamics of the circulation; by Marshall Hall and Brown-Séquard, who led the way in the experimental investigation of the functions of the various parts of the nervous system which has now reached such a wonderful stage of development.

Next to the discovery of the circulation, and almost rivalling it in importance, were the enunciation and proof of the theory of respiration. Priestley had shortly before discovered oxygen, and combustion was just beginning to be understood, when the demonstration by Lavoisier, in 1783, that carbonic acid was exhaled and oxygen absorbed by the lungs, and the comparison of the operations that resulted in this interchange of gases with the process of combustion was not merely an increase or development of previous knowledge; it was a revelation and a revolution. Until then the lungs were supposed to be simply the great and primary instrument for giving a due comminution to the blood. For the first time chemistry was brought into relation with vital operations. The original ideas, it is true, were imperfect and in some respects erroneous; but the conception of respiration as comparable with combustion was the germ of all our present knowledge of oxidation as the source of the various forms of energy developed in the system.

The full development of these ideas, however, was only possible when the doctrine of the correlation of forces and the conservation of energy was established, and it is an interesting fact that it was originally suggested by the search for an explanation of the constancy of the temperature of the body in different climates and under varying conditions.

As the microscope has revealed the intimate structure of the tissues and the mode in which they are first developed and then maintained, so chemistry has followed step by step, interpreting the connection between structure and function. The molecular changes that constitute the science of chemistry, indeed, underlie and determine the structural changes revealed by the microscope. Chemistry it is that brings us closest to the ultimate facts of life, and gives us the deepest insight into vital operations. Every vital action is a chemic action, whether the as yet to us mysterious process by which are built up the complex chemic molecules out of which the tissues are constructed or the partially understood katabolic operations by which energy is liberated.

Profound importance attaches, therefore, to the progress of organic chemistry, and those who have prosecuted its study, from Berzelius to Liebig, who led the way by analyzing the excretions and secretions and by separating and classifying the organic constituents of the various structures, down to the workers of the present day, who, by processes of inconceivable delicacy and refinement, isolate the toxins and antitoxins that play so important a part in disease, have ministered to the progress of medicine. Chemistry must ultimately form the link between physiology, pathology, and therapeutics.

Morgagni (1682–1771) may be called the founder of pathologic anatomy. He was the first to describe on a large scale, minutely and systematically, the appearances found in post-mortem examinations and to connect them with the symptoms observed during life.

John Hunter, who had perhaps a deeper insight into

pathologic processes, may be placed side by side with him; Andral and Cruveilhier later produced magnificent treatises and atlases, and since their time an enormous accumulation of facts by pathologic societies has taken place, and innumerable works on pathology have systematized the results and marked the progress made. The intent study of the changes produced by disease could not but imply a desire to understand the processes by which they were brought about. Chief among the men who have thrown new light on morbid changes and given an impulse to the study of the science of pathology must be placed the names of Virchow and Paget. With Virchow's *Cellular Pathology*, published in 1856, a new conception of pathologic changes was introduced. They were seen to be perversions of cell-nutrition and cell-activities, and diseases of the various organs were studied not as such, but as due to morbid changes in the cell-elements of the different structures entering into their composition.

Inflammation, the most common and important of these processes, has naturally been the battle-ground of rival theories. For a long time it was regarded as a purely vascular phenomenon, and all the changes in and around an inflamed area were studied from the point of view of contraction and dilatation of the capillaries and of acceleration or retardation of the current of blood through them. Then exudation of liquor sanguinis into the interstices of the tissues and proliferation of the tissue-elements were looked upon as the essential feature of the inflammatory process, and later still came Cohnheim's discovery of the migration of leukocytes. It would almost seem that every detail of the changes that take place in the course of a local inflammation is now known. With the progress of this knowledge ideas as to the nature and character of the process have completely changed. Formerly it was looked upon as destructive only; now it is recognized as, primarily at any rate, defensive—a mustering of leukocytes to oppose the invading bacillus, or a preliminary to repair of damage by the removal of structures too deeply injured to be fit for further service.

While so much is definitely known of the behavior of vessels, and blood-corpuscles, and leukocytes, and tissue-elements during inflammation, chemistry has not yet said the last word on the changes in the blood and structures. It is in virtue of some antecedent chemic and consequent physical change in the capillaries and tissues that the leukocytes are arrested and made to traverse the capillary wall, and it is not as an act of volition, but in virtue of some chemic affinity that the phagocyte englobes and disintegrates the bacillus.

The microscope has played the same important part in pathology as in physiology. The structure of all the forms of tumor has been minutely studied, and their relations with normal tissue and with each other ascertained. Degenerations of all kinds in glands, muscles, and nerve-centers have been followed from the initial departure from normal conditions to complete disintegration, and the influences under which they have taken place have been investigated.

At all periods clinical observation has been in advance of physiology and pathology, presenting problems for solution, suggesting and stimulating inquiry, and waiting to turn to therapeutic uses every addition to knowledge.

Perhaps, the first clinical discovery that brought physiology to bear directly on practical medicine was the introduction of physical diagnosis by means of percussion and auscultation, the former by Avenbrugger (1761) and Corvisart (1818), the latter by Laennec (1819). This not only brought the diseases of the chest within the ken of the physician, but opened out a new and wide field for observation. The effects of interference with the circulation by the various forms of valvular and structural disease of the heart could now be followed; the operation of back pressure through the lungs and systemic veins was traced, and the dependence of such symptoms as dropsy upon heart-disease became manifest. A most powerful impetus was thus given to experimental research. Both physiologic and pathologic affections of the different valves were indeed natural experiments on the hydraulics of the circulation.

Jenner's great discovery of vaccination, unparalleled as to the direct benefit conferred by it upon the human race, was essentially a fact of clinical observation. When, however, its significance was grasped by the genius of Pasteur it became the starting-point of bacteriologic pathology, which gives the most far-reaching insight into the causation of disease, and constitutes the most important of all links yet made out between science and therapeutics.

The employment of the thermometer in clinical work constituted another important epoch. We should now think clinical work impossible without it, but there must be yet living many who completed their studies without ever using it, and who remember its introduction by Wunderlich. The thermometer had, indeed, been employed by Coombs, but, either because medical science was not sufficiently advanced so that the profession was not ready for it, or because it was not applied extensively enough, it had not taken hold.

It is not too much to say that the clinical thermometer has revolutionized clinical observation and practical therapeutics. Before its introduction and systematized employment there could be no adequate study of pyrexia, its significance, its causation, or its effects, whether as an incident of inflammation or as the essential feature of fever, or as the fatal factor in hyperpyrexia. Till then the problem of the constant temperature of the body was not before the physiologist, and the researches as to the production and dissipation and regulation of animal heat, fruitful in so many directions, had not even been suggested. Still less had abnormally high temperatures been dealt with as such therapeutically.

Another physiologic discovery of far-reaching importance to which clinical observation has led up has been the definite determination of the fact that the ductless glands and probably other glands supply to the blood some material that plays an important part in the nutrition of the tissues, stimulating or modifying the cell-activities.

Few histories are more interesting than that of the successive steps by which extract of the thyroid gland was ascertained to cure myxedema, beginning with the observation that cretinism was associated with goiter, and that the essential feature of this affection, myxedema, could be induced by extirpation of the thyroid. Upon this, experiment showed that the cause was not the accumulation in the blood of some substance that ought to

have been withdrawn from it by the gland, but the absence of some material that the gland supplied.

Older than this, and even more important, was the discovery of the part played by micro-organisms in certain diseases. Here again clinical observation and reasoning had anticipated Pasteur. The communication of disease from person to person, the incubation-period which intervened between the exposure to contagion and the development of symptoms, the successive stages which these symptoms followed and the reproduction in the individual of the poison, had given rise to the zymotic theory, according to which the history and course of these diseases were comparable to fermentation following the addition of yeast to a saccharine solution.

Experimental demonstration, however, is now demanded, and the place of theory in medicine is only to suggest and to guide investigation. It was not, therefore, until Pasteur—by the successive steps of his work on the various fermentations on pébrine—the silkworm-disease—on malignant pustule and splenic fever—had demonstrated the powers of micro-organisms, and Lister, by that infinite capacity for taking pains, which, when combined with true insight, constitutes genius, had made the totally unexpected and unforeseen extension of the germ-theory to surgical affections; until Koch again, in 1882, had identified and made visible the *corpus delicti* of "phthisis" in the tubercle-bacillus—that the microbic origin of these diseases was fully admitted and the sweeping character of this new department of knowledge was recognized.

We may even claim for clinical observation that vaccination was a standing illustration of the attenuation of a virus, and that it anticipated and pointed the way to the processes by which Pasteur has attained such sensational results in hydrophobia and by which we hope and believe that other diseases, such as scarlatina and the fevers generally, will be robbed of their terrors.

The bounds of the zymotic theory, properly speaking, have however been overpassed, and indeed swept away, and diseases such as tuberculosis are found to be caused by micro-organisms that appeared to have no analogy with those originally grouped under the name; but science has pushed the analogy between disease and fermentation still further. Just as alcohol is the potent product of the torula, so it has been ascertained that the products of bacteria are the agents that give rise to the constitutional disturbance of disease, and these products have been separated and identified. Not only so, but just as alcohol, when it has reached a certain proportion, arrests further multiplication of the torula, so do the products of bacteria bring their action to an end, and advantage is taken of this in the antitoxin-treatment of diphtheria, which has recently evoked the admiration and challenged the gratitude of mankind.

We have still to ask, What is the bearing of all these advances of knowledge on therapeutics, which, after all, is the object of our lives?

Until the last few years it has not been easy to answer this question by instances of any very extensive applications of physiology to the treatment of disease, and morbid anatomy was at one time a stumbling-block in the way of therapeutic effort. The pathologist, pointing to an excavated lung or cirrhosed liver, would ask the physician what he could expect to do with drugs against such conditions. But that stage has passed away, and we are in a better position to combat disease as we more thoroughly understand its causation and initiation, and follow mentally its development, course, and tendencies.

Given the faculty of observation, the insight that penetrates the meaning of the phenomena, the analytic and synthetic powers by which a diagnosis is constructed, the ready adaptation of means to a well-defined end, and the firmness of character required to deal with the frailties of human nature, and the best physiologist will make the best pathologist and the best pathologist the best physician.

As regards the remedies at our command, they are only too numerous. Recourse to a great variety of drugs is fatal to exact knowledge of their effects and to precision in their use, but new ones are added every day for the benefit chiefly of those who do not know how to employ the old ones. There have, however, been recent acquisitions of extreme value, heavily discounted, unfortunately, in the case of some by the mischief done through their indiscriminate use: the antiseptic group, the chloral-sulphonal group, the salicylates and salicin, the phenacetins and antipyrin class, coca and cocain. What makes some of these, moreover, far more important and interesting is the fact that their physiologic action has been inferred from their chemic constitution.

A fact that brings practical therapeutics into near relation with physiology and pathology is that the active principles of all drugs are isolated, their chemic composition is ascertained, and their physiologic action investigated. Pharmacology, in effect, has become a branch of experimental physiology, and the immediate effect of remedies is known with a completeness and accuracy heretofore undreamt of. All this is working toward a more intelligent employment of drugs, and leads toward the goal of all the efforts to bring therapeutics within the circle of the sciences. This goal is that we should know not only the effects of remedies, but how these effects are produced. This is in the last resort a question of chemistry. All vital actions are attended with molecular or chemic changes; are from one point of view chemic actions, and come under the laws of the correlation of force and conservation of energy; so, therefore, are the physiologic and therapeutic action of drugs, and obviously the key to the latter is to be found in the chemistry of vital processes. Therapeutics, to become scientific, is only waiting for answers to the questions that she puts to chemistry. Why are sodium-salts so much more abundant than potassium-salts in the blood, and why are the former almost confined to the liquor sanguinis, and the latter to the corpuscles? We must assume that albuminoid proteids have an affinity for sodium, and the globulins for potassium. With the answer to this is bound up the secret of the necessity of sodium-, potassium-, and calcium-salts to anabolic and katabolic operations, in which they take no traceable part, and of the presence of iron in the blood-corpuscles.

Why, again, in the case of substances apparently so similar as potassium- and sodium-salts will the former, if injected into a vein, even in small quantity, paralyze the heart and destroy life, while we see pints of normal saline solution thrown into the circulation with none but good results? How does prussic acid—the simplest in composition and constitution of all organic substances—

prove fatal with such fearful promptitude by its presence in infinitesimal proportion in the blood? How again does morphin suspend the activity of the nerve-centers? Chemists must admit that the poisonous effects of prussic acid and morphin can only be due to some molecular change in these substances; they know that if the deadly cyanogen is so tied up that its component atoms cannot fly apart it is innocuous, and that a very slight change in the chemic constitution of the morphin-molecule entirely alters its effect; it is an almost irresistible inference from the doctrine of conservation of energy that the change in the molecule, say of the morphin, must be equal and opposite to the molecular change in the nerve-cells which it arrests. It seems, therefore, that we have in the chemic constitution of the morphin-molecule a clue to the character of the chemic change by which nerve-action takes place and to the quantivalence of nerve-energy.

What, then, is our position to-day in respect of the three points that we have been following—the recognition of disease, the knowledge of remedies, and the ideas that govern the employment of remedies in the treatment of disease?

The basis of therapeutics is diagnosis, the grasp of the actual condition underlying the symptoms or phenomena, and the greater our command of powerful remedies and the more precise our knowledge of their effects and of the mode in which these effects are produced, the more important does accuracy in diagnosis become.

A diagnosis, to be real, implies not only the recognition of the disease that may be present and an accurate appreciation of the morbid changes that may have taken place in various organs. It embraces also a knowledge of the nature and intensity of the pathologic processes that have been and are in operation, and of the causes that set them going, and also of the results to which they tend. A further element, moreover, enters into consideration; an estimate, by the aspect of the patient, by the pulse and temperature, and by other subjective and objective indications, of the impression made on the system, and of the resistance that it is capable of to the lethal tendencies of the disease.

Year by year we see improvement in this respect; not only that hospital-physicians and teachers endeavor to carry diagnosis to a greater pitch of accuracy and a higher point of refinement than ever before, but that the entire body of medical men are trained by improved education and systematic clinical teaching to appreciate and to practise careful diagnosis in their daily work.

Diagnosis has reached an extraordinary degree of advancement. There are, no doubt, still new fields to conquer, but in the recognition of diseases, local and general, there is not much that seriously concerns the human race which remains to be done. The same degree of knowledge, however, does not extend to morbid processes. Our comprehension of the significance and essential character of inflammation is by no means complete and satisfactory. The part that fever plays and the place that it holds among the phenomena of disease are far from being fully understood. It cannot have been intended by Nature for the destruction of the subject, and we can see distinctly that in some cases it forms part of the defensive operations; possibly, indeed, its general tendency is defensive, by promoting the production of phagocytes, or possibly a certain elevation of the temperature may be fatal to maleficent organisms which have taken possession of the blood or tissues. We are not certain, indeed, whether in pyrexia the heat-producing oxidation in the structures receives its stimulus from, or takes place at the bidding of, the nervous centers, or, on the other hand, is due to enfeeblement of the restraint that they normally exercise over it, or whether it defies control by the thermotaxic nervous centers.

Of course, our individual guide is mainly personal experience and observation of their effects. But the human mind is so constituted that it demands reasons, and even our experience finds expression in theory. There is, however, no theory that is supposed to apply to pathologic processes, and therapeutic in general, like the humoral doctrine of Hippocrates and Galen, the various iatrochemic and mechanic theories, the animism of Stahl; the stimulant, contra-stimulant, or organicist ways of accounting for everything—no theory of universal application. Yes! Homeopathy still, like a belated ghost, haunts the dawn of scientific medicine, and men are still found who wear its doctrines as a cloak for ignorance, or flaunt them as an attraction for the more foolish and credulous of the old ladies of both sexes.

But while our minds are not dominated by any *a priori* conception of a vital principle governing all vital operations, we must not flatter ourselves that we cannot be carried away by fashions in treatment. In our own day, under the influence of Todd, alcohol was largely accepted as the universal panacea, and for nearly a generation mercury was almost banished from the materia medica on theoretic grounds. The last twenty or thirty years have afforded us increased opportunities for the study of syphilitic diseases of the nervous system and of hereditary syphilis, because of the abandonment of mercury in the treatment of the primary disease. And if we have no comprehensive theory of disease or treatment we have our small working-hypotheses. To one man gout explains everything, and the more hazy or inadequate his idea of what gout is the more satisfactory the explanation. Gout, moreover, is accepted by the public as accounting for everything. The permutations and combinations of which uric acid is capable, and its ingenuity in giving rise to the most varied forms of disease, are truly wonderful. To another man the clue to treatment is acidity, or bile, or disease of the liver.

Names have still a great influence, and the lesson that Galen constantly enforced, that we must treat not the disease but the patient, is as necessary in our day as it was in his. It does not follow that because we call a pain rheumatic, the remedy is sodium salicylate.

At one time the action of quinin was supposed to be explained by calling it an antiperiodic, and any tendency to periodicity in the recurrence of symptoms of whatever kind, or at whatever intervals, was considered to be an indication for its exhibition.

It is inevitable that our imagination should be impressed by the revelation of the wonderful part that microorganisms have been found to play in the genesis of disease, and that our thoughts should turn toward antisepsis in our treatment. So far the greatest success has been in dealing with microbes outside the system, as in antiseptic surgery and preventive medicine, and further triumphs are to be hoped for in this direction, as, for example, in the prevention of tuberculosis. We have as

yet little evidence of the power of antiseptics to follow and destroy the microbes when they have once got possession of the system. Quinin, however, kills the malarial plasmodium, and we have now the antitoxic serum. Apparently, too, one virus may be antagonistic to another, and an attack of smallpox has often seemed to cure pulmonary tuberculosis. We must continue our efforts to apply antiseptic principles, but it is most important that we should not allow ourselves either to imagine that we have obtained effects that have not been realized, or to attribute results to antisepsis that may have come from other causes. It is not yet clear that any considerable impression has been made on the mortality from pulmonary tuberculosis by guaiacol or creosote; and was not sulphuretted hydrogen, injected into the rectum, to deliver us from this scourge?

It was inevitable, again, that we should be greatly struck by the remarkable power of lowering the temperature possessed by the antipyretic class of drugs. We seem to have within our reach the means of dealing with our most formidable enemy, and it is a great triumph to be able to point out to friends the effect of our remedy on the temperature-chart, especially when it has been accompanied by relief of headache and other symptoms. Here it is very important that we should maintain an attitude of cool observation, and not conclude that in bringing down the temperature we have necessarily exerted a favorable influence on the course of the disease. We may have been bringing down also the patient, and it is not so certain that Nature does not know her business when she sets up febrile reaction.

THIRD DAY—AUGUST 1ST.

MR. JONATHAN HUTCHINSON delivered the

ADDRESS IN SURGERY.

After sympathetic reference to the death of Mr. Arthur Durham, who had been appointed to deliver the Address in Surgery at this meeting of the Association, consideration was given to the work of Mr. Samuel Sharp, a former surgeon of Guy's Hospital, and then to that of M. Roux, a distinguished surgeon of La Charité. Allusion was made to the plan devised by Mr., now Sir, Spencer Wells, at that time editor of the *Medical Times and Gazette*, for the publication, in a classified form, of all operations performed in English hospitals, and the carrying out of which was entrusted to Mr. Hutchinson. At this time lithotomy and ovariectomy were new operations, and the results at first were most discouraging. Later came litholapaxy, and soon the success of ovariectomy was assured, although the operation passed through a number of stages, more particularly as regards the disposal of the pedicle. Then came the development of specialism, the good results of which gradually became evident, as it was seen that a man who thoroughly understands his subject in its details can treat it with an efficiency and ease wholly unattainable by others. A comparison of operation-statistics of the present with those of the past would show among other things an enormous increase in number. From one operation-day a week in most hospitals the number increased to two, and now there are few hospitals in which every day is not so regarded. Operations in private practice have probably increased in still greater ratio. The special operations are on the whole those that conduce most definitely to mitigate suffering and to prolong life. And perhaps the most conspicuous of these is that of extirpation of the tongue for carcinoma, the diagnosis being made early and operation not being delayed. Surgical work has also enormously increased in the treatment of diseases of the female breast, partly in connection with improved methods and partly from sounder principles of diagnosis. Concerning the extension of the medical course from four to five years, it was said that the additional year must make medical education more expensive and may possibly hinder from engaging in the study precisely some of the class that it is desirable to attract.

(To be concluded.)

NEWS ITEMS.

The American Association of Obstetricians and Gynecologists will hold its eighth annual meeting at the Auditorium Hotel, Chicago, September 24, 25, and 26, 1895. The program will include: President's Annual Address, J. Henry Carstens. Relation of Pelvic Suppuration to Structural Changes that may Occur in the Fallopian Tubes, A. P. Clarke. Nephorrhaphies, George Ben Johnston. Detached Fibroids, George H. Rohé. A Clinical Contribution to Lateral Displacement of the Uterus, Edward J. Ill. Appendicitis, A. Vander Veer. Intermediate Treatment of Puerperal Sepsis, A. B. Miller. Kraurosis Vulvæ, A Contribution to its Pathology and Therapeutics, H. W. Longyear. Report of Three Recent Cases in Gall-bladder Surgery, Edwin Ricketts. Subject to be announced, H. E. Hayd. Intestinal Obstruction Following Peritoneal Operations, A. H. Cordier. Subject to be announced, S. Y. Howell. Cure of Tubal Distention without Laparatomy, F. A. Glasgow. Subject to be announced, W. B. Dorsett. Subject to be announced, C. C. Frederick. Hysterectomy in Bilateral Diseases of the Appendages, giving Remote Results, Florian Krug. *Discussion:* Vaginal Hysterectomy *versus* Abdominal Section for Pus-tubes. (*a*) Title unannounced (affirmative), X. O. Werder. (*b*) When Shall Hysterectomy Accompany Bilateral Removal of the Appendages? Reuben Peterson. (*c*) Pathologic and Surgical Contraindications of the Vaginal Route in Dealing with Puriform Diseases of Tubes and Ovaries, Joseph Price. (*d*) Title unannounced (affirmative), George H. Rohé. *Discussion:* Eclampsia Gravidarum. (*a*) Etiology, Frederick Blume. (*b*) Pathology, George F. Hulbert. (*c*) Title to be announced, W. H. Taylor. (*d*) Prophylaxis, H. W. Longyear. (*e*) Puerperal Convulsions *vs.* Insanity, W. P. Manton. (*f*) Treatment, J. M. Duff, A. H. Wright, Thomas Lothrop. Exhibition of Various Types of Rectal Papillæ, R. T. Morris. Subject to be announced, E. Arnold Praeger. Ruptured Interstitial Pregnancy. L. H. Dunning. Has Gynecology Received Just Recognition as a Specialty? M. B. Ward. Indications for Operation in Puerperal Sepsis, L. S. McMurtry. Pneumo-peritoneum, James F. W. Ross. Subject to be announced, J. B. Murphy. Subject to be announced, Charles A. L. Reed. Subject to be announced, M. Rosenwasser.

The Canadian Medical Association will hold its twenty-eighth annual meeting in Convocation Hall, Queen's

University, Kingston, August 28, 29, and 30, 1895. The following program has been arranged:

The President's Address, Wm. Bayard. The Address in Surgery, I. H. Cameron. The Address in Medicine, Edward Farrell. A Skin Clinic, in which J. E. Graham, of Toronto; F. J. Shepherd, of Montreal; and L. Duncan Bulkley, of New York, will take part. There will probably be a Clinic on several nervous cases. Physical Training and Development as a Therapeutic Measure, B. E. McKenzie. What is the Best Treatment for Retroversion of the Uterus? A. Lapthorn Smith. A Tumor of the Medulla Oblongata, J. E. Graham. Report on a Case of Akromegaly, F. Buller. Notes upon Typhoid Fever in Private Practice, W. S. Muir. Objective Noises in the Head, G. Sterling Ryerson. Some Practical Notes on Mental Depression, J. V. Anglin. The Operative Treatment of Injuries of the Head, A. J. McCosh. Discussion, James Bell, of Montreal, and Geo. A. Peters. Final Results of Gastro-Enterostomy, Robt. C. Kirkpatrick. Dysmenorrhea, report of a case, J. Campbell. The Importance of Early Treatment in Cutaneous Cancer, A. R. Robinson. The Anomalies of Albuminuria, John R. Hamilton. Double Orchidectomy in Enlarged Prostate, E. E. King. Experimental Cachexia Strumipriva, Wesley Mills. Notes on Some of the Newer Remedies Used in Diseases of the Skin, L. Duncan Bulkley. Acute Uremia, followed by Gangrenous Abscess of the Lung, A. McPhedran. Report of a Case of Spina Bifida, with Treatment, John L. Bray. Thyroid-feeding in Cases of Stupor, C. K. Clark. Syphilitic Manifestations in the Eye, Alfred J. Horsey. The Ophthalmometer, R. A. Reeve. Notes on a Case of Brain-tumor, with an Account of its Removal, J. Webster. A Case of Placenta with Hydatids, Fetus with Spina Bifida, Alex. Bethune. The Relation of Insanity to General Diseases, E. H. Stafford. Paper, T. J. Roddick. Paper, J. L. Currie. Notes on a Case of Hernia of the Vermiform Appendix, R. W. Garrett. Paper, W. W. White. Some Unusual Forms of Hernia, F. J. Shepherd. Cases in Practice, W. G. Angin. Operative Treatment in Movable Kidney, James Bell. Asthma, H. J. Saunders.

The Medical Society of Virginia will hold its twenty-sixth annual session at Wytheville, Va., September 3, 1895. The program includes the following: Address to the Public and Profession, Dr. Lewis G. Pedigo. Annual Address of the President, Dr. Ro. J. Preston.

Subject for General Discussion.—The General Practitioner: His Duty to the Profession, to Himself, and to Society, Dr. H. M. Patterson and Dr. B. C. Keister. The Old Virginia Doctor, Dr. John Herbert Claiborne. Vesical Calculus in Females, Dr. Z. V. Sherrill. Laparotomy, with Report of Cases, Dr. James N. Greer. Strychnin as a Heart-tonic, Dr. C. K. Kernan. Convulsions, Dr. W. S. Sayers. Treatment of Cholelithiasis, Dr. George Ben Johnston. Pelvic Inflammations, Dr. J. W. Long. Uric Acid as a Gynecological Factor, Dr. T. W. Simmons. State Provision for Epileptics, Dr. William F. Drewry. Obstruction of Bowels, Dr. Hugh M. Taylor. Puerperal Sepsis, Dr. Paulus A. Irving. Seventeen Operative Cases of Chronic or Relapsing Appendicitis, with One Death—Remarks, Dr. Hunter McGuire. Varicocele, Dr. B. C. Keister. The Galvanic Current in the Treatment of Pelvic Pain, Dr. J. Allison Hodges. Title to be announced, Dr. Joseph Price. Abscess of the Liver in Children, Dr. R. M. Slaughter. A Long Survival of Injury of the Spinal Cord in the Cervical Region, Dr. James L. Kent. Pathology and Treatment of Gonorrhea, Dr. Charles M. Blackford. The Symptomatology, Etiology, and Treatment of Endometritis, Dr. George Tucker Harrison. A Case of Cerebral Trauma, Indistinct and False History—Remarks on Diagnosis and Treatment, Dr. M. J. Payne. Eye-troubles in their Relation to Diseases of Other Organs, Dr. Joseph A. White. Pyemia and Septicemia in their Surgical Aspects, Dr. J. McFadden Gaston. Rigid Os, Dr. D. Mayer. Some Recent Work in Gall-bladder Surgery, Dr. Edwin Ricketts.

The William F. Jenks Memorial Prize of five-hundred dollars, under the deed of trust of Mrs. William F. Jenks, has been awarded to A. Brothers, M.D., of New York, for the best essay on "Infant-mortality During Labor, and Its Prevention."

The Prize Committee also reports as highly meritorious the essay on the same subject bearing the motto "Vade Mecum."

The writers of the unsuccessful essays can have them returned to any address they may name by sending it and the motto that distinguished the essay to the Chairman of the Prize Committee, Horace Y. Evans, M.D., College of Physicians, Philadelphia.

Dr. James R. Tryon, Surgeon-General of the United States Navy and Chief of the Naval Bureau of Medicine and Surgery, has been awarded the bronze medal of the Red Cross Society of Venezuela, in recognition of services rendered the wounded at La Guayra during the Venezuelan revolution, three years ago, when Dr. Tryon was surgeon of the United States flagship "Chicago."

The Buffalo Medical Journal has celebrated its fiftieth anniversary by the issue of a special edition of 128 pages, profusely illustrated, and containing some 18 original articles, together with a historic review covering the period of the *Journal's* existence, and the usual editorial and other matter.

The British Gynecological Journal.—The issue of an American edition of this valuable publication, which is the official journal of the British Gynecological Society, has been begun. Dr. Luth Napier is the editor, and Hirschfeld Brothers, of New York, the American publishers.

Prof. Moos, the distinguished otologist, died recently at Heidelberg. With Prof. Knapp, of New York, he founded, in 1869, the *Archiv für Ohrenheilkunde* and the *Archives of Otology*, appearing simultaneously in Germany and the United States.

Testimonial to Sir Joseph Lister.—On his retirement from King's College, London, Sir Joseph Lister was, July 31st, presented with a three-quarters length portrait of himself, together with an illuminated and illustrated album containing the names of the subscribers.

Dr. Thomas McKennan, an eminent and successful physician of Western Pennsylvania, died at Washington, Pa., August 9th, at the age of seventy-one years.

The Tri-state Medical Society of Alabama, Georgia, and Tennessee will hold its next annual meeting in Chattanooga, October 8th, 9th, and 10th.

The Los Angeles Polyclinic is the title of a new monthly publication under the editorial charge of Dr. J. F. T. Jenkins.

For the James E. Reeves Fund.—We have received from Dr. H. A. McCallum, $1.00; Dr. J. P. West, $1.00; Dr. J. Robinson, $1.00.

BOOKS AND PAMPHLETS RECEIVED.

Chloroform in Labor. By Edwin Ricketts, M.D. Reprinted from the Virginial Medical Monthly, 1895.

Action of Certain Acidic Oxids on Salts of Hydroxy-acids. Part 1. Metallic Tartrarsenites. By G. G. Henderson, D.Sc., M.A., and A. R. Ewing, Ph.D. Reprinted from the Transactions of the Chemical Society, 1895.

Vaginal Hysterectomy as Done in France. By Edgar Garceau, M.D. Reprinted from the American Journal of Obstetrics, 1895.

Genito-urinary Surgical Clinic. Tumors within the Scrotum; A Case; Hematocele, Hydrocele, Abscess, with Old Hernial Sac; Operation. By W. B. Rogers, M.D. Reprinted from the Memphis Medical Monthly, 1895.

Laryngo-tracheotomy for Foreign Body. By W. B. Rogers, M.D. Reprinted from the Memphis Medical Monthly, 1895.

A Constriction of the Ileum by Omphalo-mesenteric Remains. By Helen C. Putnam, A.B., M.D. Reprinted from the Medical Record, 1895.

Annual Report of the Presbyterian Hospital in Philadelphia, 1895.

The Treatment of Wounds, Ulcers, and Abscesses. By W. Watson Cheyne, M.B. Ed., F.R.S., F.R.C.S. Philadelphia: Lea Brothers & Co., 1895.

On a Modification of the "Invagination" Method of Operating for the Radical Cure of Hernia. By John H. Packard, M.D. Pamphlet. Read before the Philadelphia Academy of Surgery, February 4, 1895.

Sensible Temperatures. By Mark W. Harrington, Chief of the U. S. Weather Bureau. Read before the American Climatological Association, Washington, D. C., May, 1894.

The Best Order of Topics in a Two-years' Course of Anatomy in a Medical School. By Frederick Henry Gerrish, A.M., M.D. Reprinted from Science, 1895.

Annual Statement of the Commissioner of Education to the Secretary of the Interior, 1894. W. T. Harris, Commissioner. Washington: Government Printing Office, 1894.

The Surgical Treatment of Inguinal Hernia. By Henry O. Marcy, A.M., M.D., LL.D. Reprinted from the Transactions of the New York State Medical Association, Vol. II, 1894.

The Surgical Treatment of Spina Bifida. By Henry O. Marcy, M.D. Reprinted from the Annals of Surgery, 1895.

A New Method of Resuscitating the Stillborn. By A. B. Cooke, M.D. Reprinted from the American Medico-Surgical Bulletin, 1895.

The Operative Treatment of Varicocele. By A. B. Cooke, A.M., M.D. Reprinted from the American Practitioner and News, 1895.

Typhoid Ulcer; Perforation(?); Operation; Death. Cerebral Cyst; Operation; Recovery. By B. Merrill Rickets, M.D. Reprinted from the Cincinnati Lancet-Clinic, 1895.

State of New York. Sixteenth Annual Report of the Trustees of the Binghamton State Hospital, at Binghamton, N. Y., for the year ending September 30, 1894. Transmitted to the Legislature, January, 1895. Albany: James B. Lyon, State Printer, 1895.

On Ocular Affections of Syphilis of the Brain, with Report of Five Cases. By Charles Zimmerman, M.D. Reprinted from the Archives of Ophthalmology, 1895.

Amputation of the Female Breast. By W. W. Keen, M.D., LL.D. Reprinted from the Cleveland Medical Gazette, 1894.

Amputation of the Entire Upper Extremity (Including the Clavicle and Scapula) for Sarcoma following Fracture of the Clavicle. Extensive Thoracoplasty by Schede's Method. By W. W. Keen, M.D. Read before the Philadelphia Academy of Surgery, 1895.

Ueber ein neues Heilverfahren bei Netzhautablösung. Von R. Deutschmann. Sonder-Abdruck aus Beiträge zur Augenheilkunde. Heft xx, 1895.

Report of a Surgical Clinic. Illustrated. By Prof. Augustus C. Bernays. Pamphlet. St. Louis: C. B. Woodward & Co., 1895.

Seventh Annual Report of the Department of Health of the City of Omaha, for the year ending December 31, 1894. Omaha: Klopp & Bartlett Co., Printers, 1894.

CLINICAL LESSONS.

Hysterical Contractures.

BY S. WEIR MITCHELL, M.D.,
OF PHILADELPHIA,
PHYSICIAN TO THE ORTHOPEDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES.

THESE clinical lessons are, in a measure, the offspring of opportunity. The wards have, of late, given us cases of contracture that have been so interesting and so suggestive as to tempt me to call attention to their diagnosis and especially to their treatment. The subject is in no sense exhausted.

We do not know what hysteria is. So far death has destroyed in all cases what evidence life might have offered as to its existence as an obvious thing capable of visual demonstration; and still we are apt, sometimes with too much confidence, to refer back its manifestations to this or that center. Thus, it has been taken for granted that hysterical contracture is due to disorder somewhere present in such columns of the cord as are usually diseased in cases of spastic paralysis. The chief basis on which this opinion rests is this: Cases of long-continuing hysterical contracture have been seen to end in sclerotic alterations of the lateral columns of the spinal cord. The inference is that the precedent functional states were also due to the less visible hysterical conditions of these columns.[1] Moreover, it has been taken for granted that the state of contracture is analogous to the condition we find present in muscles rendered over-responsive by lateral sclerosis.

I am not at all secure that these inferences are safe, or even that contracture is of a certainty due to spinal centers at all. It is quite possibly purely local and muscular as to origin; and, indeed, there are reasons why it is extremely difficult to consider it as of spinal birth, or in any way analogous to the state of excitability seen in disease of the lateral columns.

The history of contracture is briefly this: Under an influence, such as emotion, or from causes unknown, but usually in a frankly hysterical case, a group or groups of muscles contract abruptly or by degrees. These spasms may involve flexors or extensors, or both at once. They may affect one muscle or almost every group in all four extremities, and also the truncal muscles. This condition may last for days or years. The muscles concerned are not over-responsive to blows or to electricity. The skin-reflexes are normal or nearly so; the knee-jerk and ankle-jerk may not be in excess. Clonus is absent; if present, indecisive or brief, as we see it in hysteria or in over-excitable, weak people. The prolonged muscular action seems not to raise the local temperature. If you deeply anesthetize the patient or put on an Esmarch bandage, the muscles relax. In sleep some early cases relax; others do not. Very gentle effort in sleep to alter the angle of the limb may succeed, but the least abruptness of pull calls out a spastic response. Otherwise the spasm is constant, and efforts to overcome it forcibly give great pain. Very often there is loss of power in such muscles as are, and even in such as are not, in spasm. Usually there is profound anesthesia, confined to the disordered limbs or involving half the body.

I have said that the spasm is chronic, and this is the rule; but I have seen cases in which it came and went, or was only seen on alternate days. Quite often the flexors or extensors alone are contractured, but in the sad examples of general chronic spasm both sets of muscles are apt to suffer.

A contracture may last for years, and go as abruptly as it came—or, it is so said. I have never seen this happen, but I cannot doubt the positive statements made by others.

Under early reasonable treatment these spasms, if locally limited to single groups of muscles, are apt to get well. My own efforts to cure them with discs of metal, magnets, or by hypnotic suggestion have left me with mere histories of defeat. And yet under other treatments I often see these cases get well early. But this is not true of the more extensive contractures; in fact, the more extensive the region affected the more difficult the early treatment.

Now let us look at the graver form of multiple contracture. A patient far gone in the sad drama of hysteria has slowly, or abruptly, or after the part has been paralyzed and become insensible, a contracture of one limb, which gets worse. In a week or two the other limb suffers. Still later the remaining extremities become drawn up, and even the face, neck, belly, and thorax are involved. There are paralysis, surface-anesthesia, and intense spasm. Pain is

[1] Soc. méd. des Hôpitaux, vol. ii, 2d series, p. 24, Charcot.

rare, unless called out by pressure or motion. Usually all the muscles suffer, but the attitude is commonly one of extreme flexion, either because of the greater power of the flexors or that they are the more excited: In some cases the limbs are in extreme spastic extension, or this is the case as to the legs, and not as to hands and arms. Very early in these cases the muscle-muscle reflexes are mechanically abolished or are pathologically interfered with; and later all reflexes may disappear in the disordered parts and direct response to a blow be lost. There is apt to be diminished quantitative muscular response to faradic currents, and years after even galvanic responses may be much lessened. The anesthesia is of the surface and is apt to be at last profound.

Sleep does not relax these cases after they have existed for some months. Great but uniform wasting is seen. The muscles harden. About the joints and between the tendons a similar leathern-like hardening is found. Ether or chloroform no longer causes relaxation; nor does an Esmarch bandage, or even section of the tendons, give rise to relaxation as in the local contracture.

This is a different symptom-group. If we ask ourselves, What has happened? What is the cause? we are at once face to face with a grave and interesting problem. Without a history we would be apt enough to consider such a case as one of anterior poliomyelitis. It is but a sketch of that malady; it is not a true picture. But suppose this patient bed-ridden for a score of years. I have seen such cases, in which the cold, absolutely anesthetic limbs have lost all reflexes, and in which the shrunken muscles refuse to move under any form of electric current, save here and there to powerful galvanic alternations. The picture of an anterior spinal malady *seems* to be fairly complete.

This sad condition belongs only to the multiple contractures. It is never found in the single-limb spasm, no matter how lasting that may be. I have seen contracture of the extensors of one leg endure six years and show no sign of the peculiar permanent hardening that marks the second stage of some more generalized contractures. I recall one case in which for nine years the left gastrocnemial group remained in violent contracture. Then a section put an end to the spasm. To my surprise the muscle thus released from tension was soft and had not shrunk. In both of these cases, when under ether, the relaxed muscle behaved to electricity like a normal muscle.

All of this is unlike what happens in the contractures affecting two or more extremities. Here, even in the very early months, the muscles may begin to show a brawn-like hardness, which is a constant condition and not to be altered by anesthetics. The muscle, at first spasmodically shortened, becomes organically set and stiffened. There is still and always more or less spasm, or at least this may be the case for years. It is also possible that joint-lesions due to long disuse and to subluxations may have finally their share in adding to the complex symptom-group the element of reflex muscular contractions.

You may have already inferred that I have become quite assured that there are two forms of hysterical contracture: one apt to be local and limited and not followed by organic muscular changes; the other apt to affect two or more limbs, and almost every muscle, even of the trunk, and prone to result in the muscular and areolar tissue-changes already described. I think it curious that while the early stage of general contracture is most difficult of cure, when the disease has caused organic changes and is in its second stage it is far less hard to deal with. Perhaps this may be due in part to the disappearance of active hysteria. Indeed it is often true that in certain old examples of contracture the symptom, contracture, exists no longer, and we have to deal alone with the mischief of organically shortened muscles, altered joints, and sclerematous changes in the intermuscular spaces. The hysteria is lost with years; the spasm lessens or ceases; the consequences and additions remain.

I have said enough to enable you to separate this peculiar state from disease of the lateral or from that of the anterior gray columns of the cord. If, however, any other test be needed, it is to be found in the ease and speed with which under rubbing and faradic electricity these wasted muscles recover their characteristic excitability. With this return such reflex actions as had been mechanically obliterated again become visible, but the skin-reflexes remain absent until the anesthesia passes away.

Richet divides contractures into painful and painless. I never saw a case of constantly painful contracture in America. Some of these cases, however, become painful for a reason not always present and which only of late has become clear to me. In general the painless contracture may be made painful by quite moderate efforts to overcome the contraction, and in old cases, such as I shall describe, the pain on movement is in the joints and not in the muscles. In advanced cases of extreme contracture of the legs you meet now and then with examples of agonizing pain, apt to be referred to the feet and never seen in the arm. I had long considered this symptom as of spinal parentage. Some years ago, however, I was led in a seemingly hopeless case to suspect that the very great suffering present might be due to the stretching of the sciatic nerves at the notch and to a possible localized neuritis. A number of tendons were cut and partial extension effected. Immediate relief followed and the pain continuously lessened as extension by instruments became more complete. Encouraged by

this unlooked-for success, the case was attacked with larger hope, and in the end I had the pleasure of seeing a young and intelligent woman restored to a life of healthy usefulness. I happen to-day to have seen this woman; a strong, well-nourished, and apparently vigorous person. Looking back to the gnarled, blind, speechless patient of years ago, it seems a quite incredible rescue. Nothing except the rapid cure in this case shook my belief that very material organic change in the cord had taken place.

So far as my own knowledge goes, post-hysterical sclerosis of the cord occurs only in generalized contracture, after ten or twenty years of life in bed. In one such case I saw, after death, a moderate amount of sclerosis of the anterior columns and gray matter.

With such a symptom-group before us as I have already described as existing in old cases of multiple contracture, it is almost impossible to disbelieve the presence of more or less organic fascial change in the cord. So difficult is it, indeed, that I have often asked myself, if it may not be that organic lesions in hysterical people have a less serious hold on the tissues than such as come in the ordinary way, without precedent hysteria. Either we must accept some such conclusion or else believe that the group of symptoms delineated may occur without having for their parents organic material lesions of central nerve-cell and fiber. I trust I make clear how difficult is this problem.

It is especially interesting to me just now, because I have in my care a young woman whose case is very like that I just now mentioned as fortunate. As our first illustration of contracture and of many of the most remarkable incidents of hysteria, I shall have read to you at length this strange story of disease. It is rare that a record has been kept with the care given to this.

E. M. H., of Arkansas, was a girl fifteen years of age, whose parents were in good health, and who had three brothers and sisters alive and well. The mother had had two miscarriages; one child was born prematurely, and one died of hydrocephalus at six months. A maternal aunt was insane.

The patient was born at term, without difficulty and without instruments, and proved to be a healthy and well-formed baby. She was breast-fed for six months; never had convulsions, and, although she had scarlet fever, her childhood was fairly healthy.

She learned to walk and talk early and well; was, in fact, a bright, intellectual child. Menstruation began at twelve years, and ceased a year before the girl came under observation.

In 1890 the patient had epidemic influenza, without remarkable consequences. The present trouble began in that year. Late in March of 1890 she was running along a wet boardwalk, when she slipped at the end and fell, striking the back of her neck on the edge of the last board. She had to be assisted to rise, and complained of headache for several days. About a week later she tripped in the grass and fell, causing a green-stick fracture of the left radius. As soon as the nature of the accident was understood a plaster-cast was put on the arm, and soon afterward it was observed that the hand had begun to "draw up," and that to extend it was extremely painful. This gave rise to no suspicion, but when the cast was taken off it was found that the arm and hand were entirely paralyzed, had no sensation, a very poor circulation, had shrunk perceptibly, and were blue and mottled.

The spine was examined, and said to have been sensitive in the upper cervical region. The girl declared that tapping it at this time made the knees tremble and ache. She was ordered to bed, applications of ice made to the spine, and bromids and other medication employed. In a few days she became extremely nervous, flighty, and imaginative; had to have the room dark and still; obliged everybody to go about in slippers, and objected to the slightest noise.

Her physician concluded the trouble to be hysterical, ordered the windows opened, and suggested that her parents insist upon an effort to move the hand. The child set her own will to work as soon as she was assured that it was possible, and in a few days was using the limb tolerably well, and was on her feet again, though weak. The hand still remained partially flexed, and rather uncertain in its movements for some time afterward.

Late in June she was taken to a farm in the country, where she steadily regained her strength and flesh, playing with other children, until the middle of July, when there were four excessively hot days. Although she was kept as quiet as could be, on the fourth day the left arm dropped helpless and began to contract, and later to shrink, and became remarkably blue and mottled. Early next morning she staggered into her mother's room, complaining of dizziness. Her mother caught her in her arms, and from that time she has never stood erect upon her feet without aid. She was put in bed, and had a fever in a few days, with a temperature of from 101° to 102°. She was extremely excitable, and had a variable tendency to fancy shapes and sounds about her. Within a few days the temperature became normal. By and by she sat up and played, using both hands and arms freely, and could put out either foot to draw to her the playthings she had dropped from her hands. Still she could not stand. Twice she forgot, and springing up to answer a call dropped instantly on the floor. After waiting for two weeks, thinking she would recover the use of her legs, her parents took her home to her doctor. There was at this time an almost daily perceptible loss of power in the legs, and sensation also began to go, which had not happened before.

By October 1st, twenty-four days after the last fall, the child was without sensation below the knees. Her temperature averaged from time to time from 101° to 102°, with a very rapid pulse, and a slight return of the excitable, flighty condition. The former treatment was repeated, and again

motion was restored in ten days. The hand at this time measured three-quarters of an inch less in circumference at the first joint than the other, and the skin peeled deeply from the ends of the fingers and thumbs, so as in a measure to suggest the kind of change that is seen after an attack of scarlet fever.

From this time on there was a steady gain until September 6th, when one day she lost her balance and fell backward off her seat, striking the back of her neck, a little to the right, at the base of the brain, on the sharp edge of a sill—not a door-sill, but a part of the frame of the barn where she had been taken for her amusement. The blow raised a large lump, and was really severe. She fell doubled up between the step and the wall, and the other children pulled her out rather violently, and she complained that they hurt her back in so doing. This was late in the forenoon. She ate no dinner that day, looked pale and haggard, but said nothing about the matter. Very soon afteward it was observed that there was no motion in either feet or legs, and that the latter had begun to draw up; but the arms and hands were still untouched by this disastrous trouble.

By October 15th the knees were at a slightly acute angle, and still drawing up. Any attempt at extension caused great pain. The girl was still able to sit up, but complained that her back was constantly tired. Finally a rung was sawed out of her low chair in order to let the feet draw back under it. On October 19th, while sitting busily crocheting, her right hand fell suddenly in her lap, and a minute later the left, and neither moved again for twenty-seven months. In less than a week both arms had drawn up to a right-angle, the fingers and wrist were bent in flexion upon the arms, and both arms and legs were totally devoid of sensation. After this the child could not sit up any more, pain in the spine being constant at the lower part, chiefly in the dorso-lumbar region. The sphincter muscles of the bladder and rectum were at this time sometimes in a relaxed condition and allowed everything to pass, and at other times violently contracted so as to make the discharge of urine or feces for the time impossible.

For days the little patient was an entirely helpless person, except for the ability to move her head from side to side. About November 11th chloroform was fully administered, but the tendons did not relax, and it required the efforts of two physicians to extend the arms and legs, so as partially to straighten the joints. Next day there was a decided change for the worse. Spasmodic contractions of the neck and pectoral muscles set in. The girl could not swallow even liquids. Food was then given by injections for some days. It required an hour for her to relieve her bladder, and at this time the urine was heavily charged with phosphatic deposits, so that in a pint they were one or two inches deep.

All sorts of things happened in the next few weeks. The tongue was drawn to one side on occasions, so that the teeth rubbed the skin off it. The child became blind and nearly entirely deaf. The pectoral muscles occasionally contracted powerfully, so as to draw the arms across the chest, or to draw the chest into a deep concave, and make breathing impossible. On other occasions the head was jerked violently from side to side, even in sleep, and the girl would rise from the pillow and go to and fro with a pendulum-like motion, and then fall back, still asleep, or apparently exhausted.

There were constant spasms of the diaphragm, during which it seemed that the child would never breathe again. Her temperature during this time varied from 95° to 101°, sometimes making this extreme excursus within two hours, the pulse being then from 130 to 180, and respiration beyond the possibility of counting. Meanwhile emaciation increased; sleep became almost impossible, even with copious doses of codein, seldom lasting more than from thirty to sixty minutes, and once in twenty-four hours. At this time it was necessary to tie her head down to give her any rest at all. Ice was kept on the whole length of the spinal cord, an ice-cap was placed on the head, and in these measures the patient seemed to find more relief than in anything else. There was a broad red band across her forehead, very difficult to describe, and deep streaks down both her cheeks, of an intense red. Her eyelids sometimes remained open for long periods, and at others were shut for hours, so that she could not open them. Again, the eyes themselves would move independently, sometimes one rolling upward and the other downward, or one outward and one inward, producing a most extraordinary appearance. "Every hour for weeks," said her mother, "we expected to see her draw her last breath; nor were we alone in the belief that it was impossible that she should come out of this condition and live." "I should have mentioned also," added her mother, "to withhold nothing of interest, that she passed entire days in a comatose condition, and others in a state that could more aptly be described as a deep sleep."

During this long period the girl was fed entirely by the bowel, and was rubbed with oil and brandy, the throat and mouth being sprayed with water and glycerol every few minutes. On December 16th came what is described by her parent as the crisis. She had alarming spasms of the diaphragm, much longer than the preceding ones. Then they suddenly ceased, and did not return for three years. There was a slight relaxation at this time of all of the contractions, and the patient was rather more comfortable. In a few days afterward she began to swallow a little, but at this time she was entirely blind; she had also no sense of taste. The smallest amount of water swallowed caused extreme pain, and the slight effort of masticating or swallowing food gave rise to profuse perspiration and indescribable weakness.

It was characteristic of the hysterical nature of the case that at this time the girl could sometimes be fed by means of fancy spoons, letting her feel the patterns with her lips or tongue. About this time she began to take potassium iodid, increasing the dose as fast as the stomach could bear it.

On January 9, 1891, she was able, with effort, to tell the number of fingers held up close to her

eyes, and on January 16th could distinguish outlines and bright colors.

On March 1st her sight became good in the right eye; it had never, until very lately, returned fully to the left eye. She could see things less distinctly with the latter.

Fearing the effect of heat upon her (as she manifestly lost ground when overheated; her legs drew up more forcibly, and she lost flesh as the warm days came on), her parents were advised to take her to the mountains for the stimulus of a rarer atmosphere and the coolness of the high altitude.

A cot was made, which was swung on solid rubber ropes to save jarring, and she was carried up Roan Mountain, 6394 feet high. She began at once to sleep well, eat well, and move with ease. At this time the hands were still twisted together at the wrists, and tightly clenched. She also had the embarrassing symptom of violent protrusion of the rectal mucous membrane, which would come down suddenly in her sleep. If it was not pushed into place at once, it seemed to be caught, and then it became congested, and its return was exceedingly difficult.

At this time the legs were still contracted and motionless; both knees were subdislocated; the left foot was laid up over the right thigh, and the right foot on the left thigh. Both feet were drawn into a sharp curve, and the toes were drawn under so tightly, and so close together, that it was impossible to draw a rag under or between them. Quantities of iron and potassium iodid were given, with occasional cessation of the treatment, to let the stomach recover its tone.

The child's parents remained on the mountain with her from June 6th to October 16th, and then returned to her native town. During these four months she had gained thirty-three pounds in weight, having weighed in June forty-five pounds and in October seventy-eight pounds. On her return she instantly ceased gaining flesh, was again attacked by influenza, and was wretchedly weak all winter, and had to be watched closely, and continually kept cool, insisting upon the windows being open day and night, although the thermometer was often at zero. Her physician urged her parents to hasten away early in the spring, and accordingly they started in April, waited a month at the foot of Roan Mountain for the snow to melt, and moved over the mountain to Glen Ayres, 4500 feet above the sea-level, on the south slope. As before, the girl began to pick up at once. Sensation, which had crept down from the shoulders the previous summer nearly to the elbows, began to be manifest below the elbows.

In June, 1892, menstruation began. The girl was then twelve years and eight months old. There was no general disturbance of the system at this time, beyond slight backache and headache, and no hysterical manifestation. The menstruation continued with perfect regularity and in good quantity until December, 1893, when it ceased, and never again recommenced. There has never been any unnatural discharge or any complaint of pain or uneasiness at the menstrual period, except that caused occasionally by retention of urine.

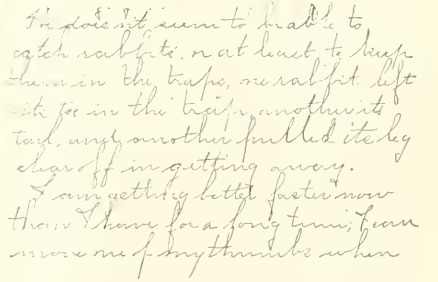
There was a general access of strength and flesh during the summer of 1892, and in September the family moved again to the summit of the mountain for the winter, fully determined to test the value of altitude in the child's case. In the meanwhile, unable to use her hands, the little one learned to write and draw beautifully with pen and pencil in her mouth,

FIG. 1.

E. M. H.: Writing with pen held in mouth.

holding them firmly on the right side between her teeth, and moving the head. She complained that the other side of her mouth was "left-handed." She

FIG. 2.



With pen in teeth, 1892.

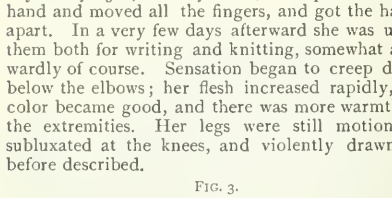
conducted in this astonishing manner a large correspondence, entirely by herself, except the folding of the letters and placing them in the envelops, the hands being still clenched and twisted as I have described. Fig. 1 illustrates her mode of writing.

The winter was extremely severe on the mountains. During January it was impossible to keep the temperature in the living-room up to 32°. Most of

the time it was from 20° to 30°. For some weeks previously the girl had been able to move her right thumb a little, and on January 13th she opened that hand, moved all the fingers, but could not separate the wrists, which, if I have made the matter clear, I should have described as being pressed violently one against the other.

January 15th, two days later, she opened the left hand and moved all the fingers, and got the hands apart. In a very few days afterward she was using them both for writing and knitting, somewhat awkwardly of course. Sensation began to creep down below the elbows; her flesh increased rapidly, her color became good, and there was more warmth of the extremities. Her legs were still motionless, subluxated at the knees, and violently drawn, as before described.

FIG. 3.



With pen in right hand, March 19, 1893.

In April she was taken to Professor Allen, of Indianapolis, who cut the cords in the groins and under the knees. The joints had grown out of shape, so that it was impossible at once to straighten the limb; and the skin under the knees had contracted and hardened so much as not to permit of their being straightened at once, after thirty-two months' flexion. A moderate amount of chloroform came near proving fatal, and so the cords were cut in four operations, whisky being given beforehand. Then extension-braces were made to be worked with ratchets, and the patient was brought back to the mountain-top. She soon sat up in a wheeled chair, rolling it with her own hands, and in fact was soon a picture of rosy, plump girlhood.

In August, 1893, she began moving her feet slightly, and resolutely practised, with the aid of her mother, until, in October, she could move the sewing-machine treadle a little. She had to lift her legs and feet with her hands, but could move her feet and toes. There was still at this time no sensation in the legs below the groin, but it was pretty good in the arms, and she could feel a needle almost down to the knuckles of both hands. The knees had been forcibly extended daily by the use of instruments until the angle was extremely slight. This process was very painful, always giving rise to great distress in the lumbar vertebra. Several attempts to stand with assistance caused extreme torment in the same region.

On September 30th the child was taken in a buckboard wagon several hundred yards, and again on October 29th; she seemed to enjoy her first and only "rides."

On November 2d she appeared languid; her back hurt her more; she could not sit up, but preferred to lie still all day. She was carried down stairs as usual to lie on a couch, and the stretching at that time was omitted and never resumed. After this she did not sit up. Two weeks later there was a slight menstrual discharge; her appetite failed, and her strength gave way. For the first time in five months it was necessary to put ice-bags on the back of her neck. In other words, she had a very serious relapse.

On December 9th she could not be carried down stairs, and was not taken down stairs again until May. Her parents had intended to move down to Roan Station for the winter, but did not think it advisable to disturb her.

Violent palpitation of the heart came on; the pulse was 160, hard and bounding; the temperature was only 97°; the respiration very rapid. At this time the physicians who saw the girl were again satisfied that it was impossible that she could live much longer.

On January 12, 1894, she had serious ulcerations of the mouth and throat; her breathing became as rapid as from 90 to 160 per minute; her pulse quick, weak, and wiry. The urine was exceedingly scanty and dark. The legs became again motionless; the cords contracted at the knees; the hips and the arms were still free, as they had been before, but increasingly numb.

At this time there came on also a great difficulty in speech. Ice was now used on the head also, and again the child desired to have all light and sound excluded. On January 20th she spoke once: "Mamma," she said, "it hurts," and never afterward, up to the time of her falling under my own care. Nor, in fact, did she make in this period an articulate sound, asleep or awake. The vocal bands were relaxed at this time, and are said to have been ulcerated. The legs were drawn almost up to the body, but there never was as much contraction of the thigh on the pelvis as of the leg on the thigh.

The girl could still express herself in writing with her hands, but complained that they were weak and numb, and she feared, as she wrote, that they were "going again." On February 10th she had violent contraction of the abdominal muscles following an enema; convulsive shudderings for a time ran over her body, and her hands and arms in an hour were completely paralyzed.

From February 10th till March 3d she had no discharge from her bowels. On February 14th she had great difficulty in expiration; she would fill her chest to the utmost degree with air, and then remain half a minute sometimes without expelling it, and finally would drive it out in jerking whiffs, her head moving violently to and fro as she did so.

At this time there was great difficulty in swallowing, and occasionally swallowing was followed by some violent convulsive efforts, during which the blood would fly forcibly from the nose and mouth. Two hours or more were required to swallow two or

three ounces of milk, and nourishment was mainly given by enemata. At this time some effort was made to knead the bowels, but every attempt caused contractions of the bowels so violent that the muscles would spring into stiff cords, and thus remain for hours, while the urine had to be drawn away, and was brown and exceedingly offensive, but without blood.

The difficulty in expiration of air lasted until all the spastic contractions had ceased, and the legs were motionless, like the limbs and head, the child using the diaphragm only at brief intervals. At this time codein was used hypodermically.

On March 3d there was a temporary cessation of contractions, and the bowels were moved, and this was the last motion until March 29th. During all this time the patient was fed chiefly by enema; nothing passed away, everything being absorbed with astonishing ease.

After February 10th all communication was made by the eyelids; the child could no longer use her hands or her speech, even in the faintest whisper; but when she wished to indicate anything she would wink several times, and cards were held up containing the alphabet, and when the right letter was reached she would wink.

On March 12th continuous convulsions of the head, arms, bowels, jaws, and tongue set in. All food and drink were given by the bowel and by outward application. Again there was a deep crimson flush all over the head, and it was needful continuously to keep ice on the neck and head. The facial and temporal arteries were of the size of large lead-pencils; all were throbbing so violently that their pulsations could be counted across the room.

On March 22d the convulsions were so violent as to require men to hold the child, and at this time it was observed that the urine became of an extraordinary odor, described to be like that of the cat. On March 25th she was totally deaf, partially blind, and entirely speechless. She could not feel a needle anywhere in the body, except in the lips. The skin was rough all over the body, and looked and felt like sand-paper, presenting an indescribable dry roughness.

At this time any attempt to comb the hair was followed by bleeding from the scalp, and the hair fell out in handfuls. Emaciation became extreme. All of this time the girl had an exceeding sensitiveness as to heat, and the breathing would become terribly difficult if the windows were closed, so that her family were obliged to keep the sash up and the transom over the door open on the top of the mountain, with the thermometer frequently down in the neighborhood of zero. Her nurses, as may be imagined, suffered severely under this *régime*.

On March 29th her convulsions ceased. On April 4th she had discharges of green and yellow pus, in remarkable quantities, from the ears and nose, as well as from one or two abscesses, which had to be opened, in various parts of the body; one on the side of the neck appeared to be very serious. Shortly after this her sight began to return, and it was soon found that she was reading the motions of her attendant's lips, although stone deaf, and very soon she understood every syllable, when the light was good and faces were turned squarely toward her. From this on for months she continued to improve in this accomplishment. Her family learned for her use the deaf-and-dumb alphabet, so that she communicated with them either by speaking with her own lips, so that her mother read them, or by looking at the lips of those talking, or by seeing the motion of her mother's fingers, when her sight at length was better. Following this there was a period of many months during which she was subject to curious and frequent attacks of congestion of the superficial veins all over the body. The whole body would sometimes become mottled blue, as if a coarse blue veil were drawn over it; the lips and eyelids would grow almost black, and breathing become exceedingly difficult. It was then necessary to give stimulants quickly, and to sponge the body with cold and hot water, and renew the hot-water bottles, and do quick work, in order, as it seemed to her family, to save the child from death. A little excitement, or a too warm room, would in a minute bring on one of these remarkable attacks. The last attack of this sort occurred in September.

Early in May she began to chew a little; she could swallow no solids, and only from one-eighth to one-fifth of the fluids attempted; the diet was still chiefly by enema. On May 2d Dr. Allen, who saw her, expressed his surprise that she was still alive, and it did not seem possible then that she could live from hour to hour, although she had been really convalescing for nearly a month. She was breathing entirely with the diaphragm at this time; the lungs were congested and full of râles, and up above (that is to say, in the costal region) quite motionless.

From this time there were gradual gains, and it seems useless to repeat the roll of extraordinary hysterical symptoms. Early in June she began moving the fingers of the left hand. On June 13th she was able to "shake hands all around," as she said, and could swallow a little solid food, and nearly all liquids. On June 19th she wrote her name for Dr. Allen and for her mother, and respiration began to be deeper and more comfortable, and she was more cheerful and happy.

On September 13th she was moved down to Roan Station, 2650 feet above sea-level, where the air was not so rare as before. On September 28th, the third consecutive warm day, the mercury being at 80°, a violent inflammation of the eyeballs and eyelids and congestion of the entire face and neck came on, and lasted until the weather changed, a week later. At this time the child began to make her right hand hold the work for her left hand. The left hand and arm were quite free and vigorous, although there was no feeling as yet in any part of them.

Every warm day in October and November brought back symptoms similar to those already described, but the prompt use of cold applications stopped the attacks.

On November 26, 1894, four years and three months after the second injury, and four years and

nearly eight months after the first injury on the boardwalk, and thirteen months after the last relapse, the sight was good in the right eye; dim in the left eye. The ear-drums were said to be congested, but she distinguished many sounds through a trumpet, if one spoke loudly; and almost all the alphabet, except *w*, after four or five repetitions. Often she could not distinguish both syllables of a two-syllabled word, not even her own name. After the first efforts her deafness seemed to increase. At this time she heard the letters better on cold days than on warm days. High-pitched voices hurt her.

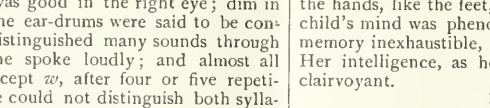
On examination of the ears no perforation of the drums was found, in spite of the free discharge from the ears. Inflation of the Eustachian tubes was attempted, but could not be borne. No effort at articulation was possible. Comparatively little food could be taken, but it was swallowed more freely, and only a little thrown out by the tongue, although some food was still given by injection.

Although there was a gradual gain in flesh and strength, sensation returned late in both arms above the elbows. The right hand recovered its motion and held the work so as to enable her to use the needle with her left hand; or else she would hold the pen in the right hand for writing, and guide the whole organ with the left, seizing it at the wrist with the left hand.

The limbs remained unchanged, the feet crossed and drawn. The patient lay nearly all the time at this period on the right side, and could not bear lying on the spine at all. There were a great many râles in the right lung, and what was described as emphysema and congestion, but the pulmonary condition was better than a month before. The temperature was usually half a degree above normal; the pulse always a hundred or more, and easily increased. The girl at this time could not bear a temperature of over 70°, whether natural or artificial, and had to have plenty of air. The stomach could not hold much food at a time; efforts to feed her produced contraction and pain and a threat of return of bad symptoms. The bowels were only moved by copious enemata; the discharges were slow and difficult, by reason of weakness. A good deal of mucus passed, frequently in large shreds. The bladder was subject to involuntary and frequent passages. The child was aware when these would begin, and could sometimes, though not often, start them, but could not stop them. The skin had become natural in texture and of a good color. There had been no bedsores recently; there had been one on the head in March, but it had healed up very readily. The right ear, I should say, had a large piece worn out of the rim—a deep notch caused by the jerking of the head on the pillow in February and March of the year before. This had long since healed. The spine was very tender; the child could not bear to have it touched; the muscles alongside of it were also very sensitive.

The mother added that at this time the girl was fifteen years of age; that she had grown symmetrically in the main; that if she ever walked she would not be noticeably under-developed anywhere. The feet were rather small, but not deformed; and the hands, like the feet, were of good shape. The child's mind was phenomenally clear and keen, her memory inexhaustible, and her patience very great. Her intelligence, as her mother said, was almost clairvoyant.

FIG 4.



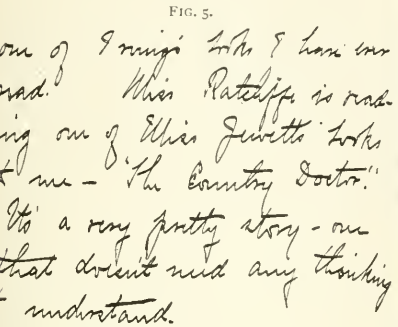
With pen in left hand, November, 1894.

In December, 1894, this child was brought to me: a bright, exceedingly intelligent, very pretty girl, less thin about the face than elsewhere, and sufficiently developed for her time of life. There was marked general emaciation, which was most marked in the right arm; the weight at this time was about sixty pounds. There was great contraction of the legs upon the thighs, so that the heels lay up against the buttocks, and the feet were crossed, one ankle over the other. The contraction of the thighs upon the pelvis was not much beyond a right-angle. The knees were closely drawn together. It was impossible forcibly to straighten the legs, even after complete use of chloroform, and the joints were secondarily affected, the knees partially luxated. The skin of the limbs about the ankles and knees was thickened, shining, and smooth, and in the cracks of the joints, as behind the knee, was excessively hard and tough, as though there was infiltration of the areolar tissues, it being difficult to feel the tendons distinctly. The temperature of the legs was good above the knees, but the feet were exceedingly cold, although there was nothing remarkable about the nutrition of the nails, either in the feet or hands. The cutaneous, muscular, and tendinous reflexes were all absent, and pins could be stuck in anywhere below the hips without evidence of pain. Neither was there any thermal sense below the groin or in the right arm.

Over and above the contraction in the muscle there appeared to be also a true paralysis of motion below the knee, as the child was incapable of making the slightest exhibition of movement of the toes or ankles. She could lift and hold both arms up from the bed. She could not grasp anything with either hand, but with a little management and support could hold a book. There was no very complete loss of power in the upper limbs to localize a touch or to detect extremes of heat and cold. Pain was here unfelt, and there was analgesia over the whole trunk. The biceps tendon-jerk and the muscle-jerk of the extensors of the hand were, however, present. Respiration was normal, about eighteen to the minute; the heart, lungs, and bowels were natural; there was no evidence of

organic disease in the abdomen or elsewhere; the urine was normal. The sight was good at this time;

Fig. 5.



With pen in right hand, guided by left hand, March, 1895.

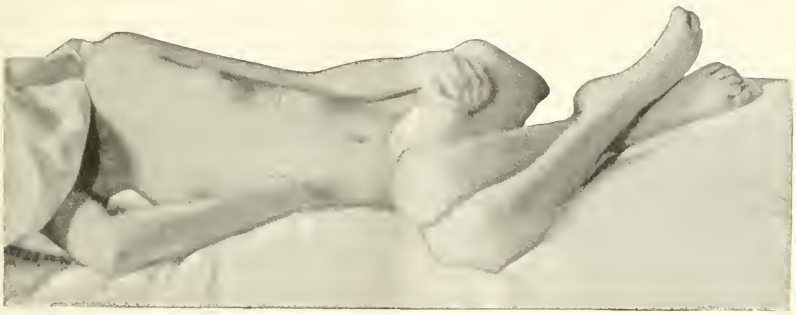
the pupils were equal, moderately dilated, and reacted well to light and in accommodation.

more difficulty, explaining that it was on account of the moustache which hides the lip.

Dr. Archibald G. Thomson examined the eyes and ears, and reported as follows: O. D. The media are clear; the pupil clear and reacting normally. The disc is normal and color good, with a small central cup. The vessels and the fundus are normal, 4–1, with astigmatism. The fields for form and color are normal. O. S. The same as the right, except that the astigmatism is a little higher. The muscular balance is slight. Exophoria due to weakness of internal rectus. There is no perforation of the tympanic membrane or other gross lesion of the ears.

This child remained at rest in bed on her side always. To be on the back caused lumbar ache. Before attempting any more serious step I endeavored to see how much movement I could get in the legs by the continuous use of massage and faradic electricity. Very soon I found that there was a slight increase of sensation everywhere; that the limbs were beginning again to grow; that they could be drawn down each day a little lower, and

Fig. 6.



E. M. H.: Attitude before treatment.

Fig. 7.

E. M. H.: Attitude after fifteen days' treatment.

The child declared that she was absolutely deaf, and made no attempt to speak whatsoever. She read her mother's lips with ease, and mine with

that the temperature of the feet increased. After a few weeks of this treatment we ceased to gain any further power of passive extension of the limbs, and

it became obvious to me that, however reluctantly, I must resort to surgical interference.

Meanwhile her deafness interested me greatly. It became rapidly well in a few weeks. Speech came back with nearly as great speed, so that within two months after she fell into my hands she could speak perfectly well, could hear entirely well, could see as well as ever, and was recovering pretty rapidly the use of the left arm and more slowly the right. She had made also great gain in motion and sensation in the lower limbs above the ankles.

At this time I requested Dr. Keen to make sections of the tendons of the leg, one at a time, and this was done with great difficulty under profound etherization; partial straightening of the leg was accomplished then, with weights and apparatus, but not with the ratchet. There has been a gradual extension of the left leg, and it seems likely that it will continue to improve, although the previous history prepared me to see at any time some return of hysterical phenomena.

On April 26, 1895, the left leg was so much better that Dr. Keen thought it would be well to operate on the right leg. Sections of the tendons at the knee were made, but it was found that the head of the tibia was so luxated posteriorly as to render impossible such extension as had been effected on the opposite side. After a time a suitable apparatus may overcome this unfortunate mechanical difficulty, but much will depend on her endurance, and the gain to be hoped for from massage and electric stimulation.

Of the drawings, Fig. 6 represents the attitude of the child when she first came under my care; Fig. 7 the results obtained by massage and electricity and slight extension by weights, up to the date of operation; and Fig. 1 the position in which she placed herself when using her pencil or pen with her mouth. I also add *fac-similes* of parts of letters, written with her hands and with the mouth. (Figs. 2, 3, 4, 5.)

As a clinical lesson in hysteria, nothing could be more instructive than this record. I have little doubt that early isolation and resolute treatment would have saved these years of distress. Before we pass on to consider the gravest system—the general contractures—I desire to call your attention to the fact of the absence of changes in the fields for color and form—surely an amazing thing in a case with so much anesthesia. Unlike the case first spoken of, the wasted leg-muscles, especially the flexors, can be stimulated by faradic currents; but the current that moves them so slightly is one that I cannot endure, and that painfully cramps any of my muscles on which I test it. Electro-muscular sensibility and irritability are very much lower. Those muscles of the limbs that are made tense by long contraction of their opponents scarcely stir at all with the utmost power of a battery, but when I relax them somewhat by forcible extension of the limb the relaxed extensors move better under faradic excitation. This corresponds with the curious observations reported long ago by Morris J. Lewis and myself to the effect that forcibly stretched muscles not only move badly under electricity, but also do not feel it so keenly. Had not these muscles been once shortened by tendon-section and their sequent elongation I should have begun by cutting them. I felt that again to cut these tendons would result in further additions to their lengths and that I should run great risk of seriously disabling their strength. Nevertheless I shall be forced, soon or late, to take this risk. In a long experience with hysterical contracture I have never before come face to face with this difficulty. Of course, there is always the after-resource of shortening the tendons.

Seeing how great is the power with which the muscle in a state of spasm contracts, I used to fear that its retraction after surgical section of tendons would be excessive. It is not so. Rather does the sudden cessation of tension appear to put the muscle at rest, as though the resistance were one of the means of keeping up the pull made by the muscle. I have, in fact, lost the fear I once had as to section of hysterical muscles or their tendons.

In the case of Miss C.,[1] of which I have already spoken, there was extreme pain in the feet. In another case, to be presently described, there was a like torment. In the one just now related there has been little or none. The reason is, I think, this: While the flexion at the knee is in this latter extreme, that of the thigh on the trunk is not. In Miss C.'s case not only were the knee-joints at the utmost angle of acuteness possible, but the knees touched the chin, as was nearly the case in the man in Scott Ward, of whom I shall have more to say by-and-by. Now flexion at the knee only relaxes the sciatic nerve, but extreme flexion of the thigh on the trunk keeps the nerve tightly drawn over the edge of the notch, and may well be—indeed was, I am sure—the chief cause of pain in two of the cases referred to. In both, tendon-section and even partial extension of the limb speedily put an end to the pain in question. In my last case, the absence of pain is, I think, due to the lack of extreme flexion of the thigh on the trunk.

There are other interesting features in this case with which I can deal but lightly. One was the rare symptom, deafness. It was complete; nor did the most unexpected and violent sounds enable me to detect the patient in simulation. With Malony's ear-tubes she began to hear a little, and with her general gain the deafness speedily departed. I should not, above all, forget to say that for the first time in her history she was isolated from her relatives.

(To be concluded.)

[1] Lectures on Nervous Diseases, p. 227.

THE PUPIL IN HEALTH AND IN EPILEPSY.

By WENDELL REBER, M.D.,
OF POTTSVILLE, PA.

Pupillary inequality, technically termed anisocoria, is a sign that has been little studied in the healthy subject. In treating of pathologic conditions frequent reference is made to it, but as to its frequency in health, facilitating comparative study, there is practically nothing said of it in the text-books, and but few pages devoted to it in the literature. A comprehensive treatment of the "Pupillary Reaction" by Haddaeus[1] and a second paper by Iwanow[2] comprise the main contributions to this topic in the last ten years.

The matter of inequality of the pupils in its relation to epilepsy has in recent years been brought forward by several observers. In the *Journal of Nervous and Mental Disease* for 1893 Browning, of Brooklyn, discusses at some length the frequency of anisocoria in the interparoxysmal periods of epilepsy, and refers to the existence of this sign in its latent form. This, I believe, is the first mention of "latent pupillary inequality."[3] In opening the subject this writer states that "the condition of pupillary inequality is not very rare, even in persons of average health; that no great importance attaches to it in any class of troubles, but as an objective sign it is worthy of further study." After recording statistics he observes further: "As to the proportion of anisocoria in non-epileptics, or as to what proportion of the above cases may be due to local anomalies of the eye itself, we have no figures for comparison."

It will be the purpose of this paper first to direct attention to the percentage of anisocoria—manifest and latent—occurring in persons of average health, and then to consider pupillary inequality as seen by myself among a number of epileptics at the State Hospital for the Insane at Norristown, Pa., during my residence as interne at that institution.

Of anisocoria in health there is little to be found anywhere, as I have said. De Schweinitz[4] makes mention of it only in a foot-note, in which he briefly records the finding of Iwanow.[5] The latter investigator made his observations on 134 healthy young recruits, and found an equal width of pupil in but 12 of them. The right pupil was larger in 49, the left in 73. The face was asymmetric in 131, the left half being larger in 99, the right half in 32. Iwanow believes that "an unequal width of pupil does not always have a pathologic significance."

Fuchs,[1] after explaining the consensual reaction to light and the connection existing between the oculomotor nuclei of both sides, producing simultaneity of action, concludes that "inequality of the pupils is always pathologic." To my mind, having myself found in 50 selected healthy cases slight unequal width of pupils 7 times, it seems safe to assume that our Viennese author refers to an inequality both manifest and gross.

From my case-records I have tabulated the pupillary conditions in 50 cases presenting vision of $\frac{5}{6}$ or better, most of which applied for relief from slight refractive anomalies. The list includes both sexes. It embraces work that antedates my interest in latent anisocoria, and will serve therefore only in studying manifest pupillary conditions. The dimensions noted in each of the records mentioned have reference to the condition of the iris when unaffected by the associated acts of convergence and accommodation, as it is my practice when observing the pupil to have the patient survey a distant object. In this series of cases taken from both sexes there were found five anisocorics, a proportion of 10 per cent.

During last summer, through the kindness of the United States recruiting officer at this point (Pottsville), it was my privilege to examine the eyes of a great number of applicants for enlistment in the army. From these I have tabulated 50 cases, with the view of ascertaining the percentage of anisocoria—both varieties—existing in healthy subjects. By examining males only any conflicting findings that might be the result of special feminine characteristics were avoided. All of these applicants were fine examples of physical manhood and well-being, presented normal eyes, and had vision of $\frac{5}{5}$ or better. The following course was pursued in each case:

1. Subjects were chosen whose eyes were free from tissue-changes in all the media and tunics.

2. The complicating influence of convergence and accommodation was excluded by proper measures.

3. The observation for manifest pupillary inequality was conducted under full indirect solar illumination (diffuse daylight).

4. That for latent anisocoria was made with illumination from the ophthalmoscopic mirror as in ordinary ophthalmoscopy, using a three-fifths-inch flame on an argand burner, this amount of light at a distance of one foot being just sufficient to carry on examination in a well-darkened room.[2]

[2] Iwanow: Arch. of Ophthal., vol. xvi, p. 464. On the reaction of the healthy pupil.

[3] Manifest inequality refers to the occurrence of unequal pupillary areas under full monocular exposure to diffuse daylight.

Latent inequality occurs when the pupils are equal under full monocular exposure to diffuse daylight, but differ in size when in a passive condition in a darkened room, the pupil being illuminated by a feeble light from the ophthalmoscopic mirror as in ordinary ophthalmoscopy.

[4] Text-book, p. 264.

[5] Op. cit.

[1] Text-book, p. 261.

[2] It was understood that even more exact results, had it been desired, could have been obtained by estimating each time the

In this way a minimum illumination of constant intensity is obtained. In a darkened room, with the patient's back to the light, the pupil dilates two-thirds, averaging 6 mm. The first impact of the light from the ophthalmoscopic mirror on the retina sets up primary iridic contraction, but after a few oscillations the pupil remains at about 6 mm. By throwing in the light from either side of the eye the minimum retinal stimulus is produced, and the resultant oculomotor reflex held as nearly as possible in abeyance, thus revealing the slightest discrepancies in size. Therefore peripheral retinal stimulation only was employed in estimating the latent pupillary condition.

5. In examining for either manifest or latent conditions monocular exposure was used in the determination.

6. Owing to the difficulty of observation under feeble illumination differences in the pupil of less than ½ mm. were not considered.[1]

1. The same routine examination was adhered to in each case, thus obviating the possibility of different results arising from different methods of study. Care was also taken that each examination was made under the same conditions.

A study of the table growing out of this second series of cases shows that under full exposure to diffuse daylight anisocoria was present in 7 of the 50 cases—14 per cent. Under feeble artificial illumination it was observed in 20 of the 50 cases. Of these 20, 4 exhibited inequality under both strong and feeble illumination, and therefore fall out of the count in considering latent anisocoria. This leaves 16 cases (32 per cent.) presenting demonstrable latent inequality. In explanation of this large proportion of pupillary inequality under feeble light-stimulus, it should be observed that the measurements were exact and the differences slight; in 16 cases the difference between the pupils was ½ mm., in 2 cases 1 mm., and in 2 cases 1½ mm. In this latter series the average diameter of the pupil in diffuse daylight was found to be 3 mm., while under ophthalmoscopic illumination it was 6 mm. The average excursion of the iris was therefore 3 mm.

Taking the statistics of this series, in conjunction with those of the previous one, we find in 100 subjects, free from disease, inequality of the pupils in 24 (24 per cent.).

In passing to the consideration of this pupillary sign as related to the epileptic interval, it would be well for purposes of comparison to note the findings of others. Schleich, Marie, and Oliver conducted their studies on institution-inmates. The first-named observer found the condition in but 4 per cent. of his cases, while Marie and Oliver show a frequency of 15 per cent. Musso records 22 per cent. in 70 cases, and Addison 4 per cent. in 50 cases. This wide diversity in statistics must find its explanation, as Browning has it, "in varying closeness and time of observation." Browning's study of 150 consecutive dispensary-patients at the Long Island Hospital revealed 16 cases. Of this 16, 3 exhibited Jacksonian, secondary eclampsic, and tabetic symptoms.

In my work at the Norristown Asylum I had occasion to study 22 selected cases of epilepsy. Among these were 4 which, though of traumatic origin, manifested no Jacksonian symptoms; in fact, the whole symptom-complex was that of non-focal epilepsy. The precautions as to exclusion of improper cases and adherence to a routine method of examination under the same conditions, as noted in connection with the work on healthy individuals, were rigidly observed in this last study, in the hope that the findings might approach as nearly as possible to absolute accuracy. Additional care was taken in this series that each case be examined in the interparoxysmal period.[1]

Analysis of the resultant table shows that in 22 cases of epilepsy, anisocoria of some degree was present in diffuse daylight 5 times, or in a proportion of 22⅞ per cent.

Let us now group the findings:[2]

Observer.	No. of cases examined.	No. of times anisocoria found.
Marie	53	8
Musso	70	16
Oliver	50	7
Browning	150	16
Reber	22	5
	345	52

Thus, in 345 observations made by different investigators, anisocoria was found in the proportion of 14½ per cent. The foregoing figures agree pretty well, and it seems safe to assume that 1 epileptic in 7 will present some manifest pupillary inequality.

So much for the general opinion as to the frequency of manifest inequality. As to latent inequality in epilepsy, there are few figures for comparison, Browning's being the only ones I have been able to find. This observer points out the varying and deceptive influence of light and shadow in making estimations, and recommends trying the light from both sides before deciding, using a dim,

photometric equivalent of the flame in the argand burner, but it was felt that for purposes of scientific accuracy the method adopted was adequate.

[1] The measurement of the pupils was made with a pupillometer marked in half-millimeters, careful account of the corneal aberration being taken.

[1] No patient was examined within twenty-four hours of a seizure.

[2] Addison and Schleich not included. It is felt that they recorded only gross differences in the pupils.

diffuse daylight. He states that "even with this precaution it remains a relative matter so far as estimating the degree of illumination is concerned." He found 2 instances of the latent phenomenon in the last 50 of the 150 cases he examined, though he remarks that, had the condition been carefully sought for in his previous 100 cases, the proportion might have been increased.

The method of studying the passive or latent condition of the pupil in healthy subjects, noted in the second series, was rigidly adhered to in studying this phase of the pupil in epilepsy. All the precautions there thrown out were here observed, and, as in my preceding study of epileptics (of the manifest condition), examinations were made only in the intervals between seizures. In this manner inequality of the pupils was found 8 times in the 22 epileptics. Of the 8 affected cases, 2 presented unequal pupils in diffuse daylight, and cannot therefore figure in the calculation. There remain 6 cases of undoubted latent pupillary inequality in a total of 22 examined. It must be remembered that all of the 22 were asylum-cases that had been committed to the institution because of the chronicity of their affection. Of the 6 cases presenting latent anisocoria, 1 was twenty-one years of age, 1 was thirty-five years, and the remaining 4 ranged from 40 to 50 years. Hence it would appear that latent inequality appears dominantly among old epileptics in whom degenerative changes have been wrought; in whom frequently repeated functional disturbances have finally produced structural changes, and physiology has passed over into pathology. It seems also probable that the proportion of latent anisocoria here found (27⅓ per cent., or 6 in 22) represents its highest frequency, inasmuch as the terminal degenerations found in institution-inmates are favorable to the occurrence of the phenomenon.

For comparative study I shall contrast the different series.

1. *Comparing manifest and latent anisocoria in health.*

In 100 healthy subjects (my own cases) inequality of the pupils was found in diffuse daylight 24 times (24 per cent.).

In 50 healthy selected cases (all young army-recruits examined by me) the pupils under feeble artificial illumination (latent anisocoria) were found unequal 16 times (32 per cent.).

2. *Comparing manifest anisocoria in health and epilepsy.*

In 345 epileptics (examined by various observers) inequality of the pupils was found in diffuse daylight 49 times (14½ per cent.).

In 100 healthy subjects (my own cases) inequality of the pupils was found in diffuse daylight 24 times (24 per cent.).

3. *Comparing latent anisocoria in health and in epilepsy.*

In 22 epileptics (my own cases) the pupils were found unequal under feeble artificial illumination 6 times (27⅓ per cent.).

In 50 selected healthy cases (all young army-recruits examined by me) the pupils were found unequal 16 times (32 per cent.).

4. *Comparing, lastly, manifest and latent anisocoria in epilepsy.*

In 345 epileptics (examined by various observers) manifest anisocoria was present 49 times (14½ per cent.).

In 22 epileptics (examined by me) latent anisocoria was present 6 times (27⅓ per cent.).

In Comparison No. 1 we find just what would be anticipated, namely, that when the oculomotor control of the pupil is removed, even in health, pupillary inequality reveals itself more frequently.

A first glance at Comparison No. 2 would seem to indicate that manifest anisocoria is more prevalent in health than in epilepsy. It is my impression, however, that, had the same searching scrutiny been exercised in the epileptics that was bestowed upon the healthy subjects, the proportion would have been found about equal.

Similarly in Comparison No. 3, in which the greater proportion of latent anisocoria would seem to obtain in health, it is my belief that, had I employed the same accuracy in my study of the epileptics (who were examined first) that was afterward observed in the study of the selected healthy cases, the proportion here would have been about equal.

In Comparison No. 4 we again find latent anisocoria the more frequent, and also, as would be expected, the relative frequency of latent inequality is much greater in epilepsy than in health. As the passive condition of the pupil is dominated by the sympathetic nervous system, we would naturally find oftener in epilepsy, in which the equilibrium of the sympathetic nervous system is unstable, an inequality in the pupils. The phenomenon accords very well with Browning's conception that "whilst the passive (*i. e.*, sympathetic) innervation of the irides is in such cases unequal or disproportionate, the reflex impulse—equal for the two eyes—is, when fully called into play, quantitatively so far in excess as to overbear completely all passive ones, and so for the time being to wholly dictate the pupillary condition. The relative superiority of the oculomotor control of the pupil, as compared with the sympathetic, is, of course, a matter of every-day observation. This explanation interprets the morbid phenomenon as a symptom resulting not simply from bilaterally uneven sympathetic action, but as one that only appears at times when the action of the oculomotor is relatively or absolutely in abeyance."

Hence we distinguish

1. A passive or latent anisocoria.

2. An active or manifest anisocoria.

The origin of active or manifest anisocoria must be considered in its relation to the oculomotor nuclei situated in the fourth ventricle. However, it would be foreign to the purpose of this paper more than to mention this point. It will be more fully considered in a future paper.[1]

From my studies I incline to the belief that the frequency of manifest pupillary inequality in epilepsy is nearer 20 than 15 per cent., and that when investigators have failed to show that amount their work has been lacking in closeness of observation. I further believe that about one epileptic in four will exhibit some latent pupillary inequality.

While I realize that my work is open to the criticism of insufficiency of data, I feel justified in drawing the following tentative conclusions:

1. That pupillary inequality, even of considerable degree, is not always pathologic.

2. That in order to demonstrate latent inequalities the oculomotor influence must be as nearly as possible set aside.

3. That in health latent inequality is more frequent than the manifest form, in the proportion of 4 to 3.

4. That in epilepsy the latent form of the anomaly is more frequent than the manifest in the proportion of 2 to 1.

5. That it is only of relative importance in epilepsy, and can occupy but a minor position in building up the objective picture of that disorder.

RECENT MEASURES FOR THE PREVENTION AND TREATMENT OF TUBERCULOSIS.[2]

BY GUY HINSDALE, M.D.,
OF PHILADELPHIA,
MEMBER OF THE AMERICAN CLIMATOLOGICAL ASSOCIATION; MEMBER OF THE PENNSYLVANIA SOCIETY FOR THE PREVENTION OF TUBERCULOSIS; FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA, AND OF THE AMERICAN ACADEMY OF MEDICINE, ETC.

A BRIEF review of the extensive provisions for tuberculous patients abroad shows how far behind America is in the systematic care of this large class of sufferers. I do not, of course, refer to provision for those who are able to command, in addition to skilled medical attendants, the measures that promote recovery, and especially the advantages of favorable climates; but rather the hospital-class, of far greater extent, who need the housing, food, and care that they are unable to purchase. The well-to-do are at least as well provided for here as in Europe; but our State governments have not, to any appreciable extent, definitely helped the dependent class in this regard. The English began to look after the tuberculous more than a hundred years ago. An institution for their relief was established in Kent as early as 1791. The Hospital for Consumptives and Diseases of the Chest at Brompton, which was established fifty-four years ago, now has a capacity of 315 beds and an income of over one-hundred-thousand dollars. Other hospitals have been erected at Torquay, Bournemouth, and Liverpool; and in 1869 the Royal National Hospital for Consumption and Diseases of the Chest, at Ventnor, Undercliff, Isle of Wight. The last includes twenty buildings picturesquely situated, and has a capacity of 134 patients. Altogether, England has eighteen institutions of this character, which receive annually between 6000 and 7000 patients.

France has institutions at Berck-sur-Mer, Arcachon, Cannes, Argeles, founded in 1878, Touraine at Ormesson, and Villiers on the river Marne and Villepinte. The city of Paris has also erected a large sanitarium for indigent tuberculous persons at Agincourt, with a present capacity of 100, and provision for enlargement.

Germany has an institution for the tuberculous at Falkenstein in the Taunus, near Frankfort, under the care of Dr. Dettweiler. One at Ruppertshain, in the same neighborhood, is being erected for the accommodation of seventy-five. In 1893 an institution was opened at Rehburg, in Hanover, for the tuberculous poor of Bremen; it has provision for twenty-four beds. In the first ten months sixty-nine patients were admitted and about one-third were able to return to their occupations.

At Malchow, near Berlin, an institution was established in 1892 for men in any stage of tuberculosis. It has a capacity of 100, and cost $50,000. At Gütergotz, also near Berlin, a similar institution for eighty patients is projected; another, to cost 250,000 marks, is to be erected at Reiboldsgrün, at an elevation of 2160 feet, where there is already a small institution for persons of means. The city of Worms is also adopting similar measures for its tuberculous; so also in Würzburg plans are being formed to erect a sanitarium at Spessart. At St. Andreasburg and Blankenhain in the Hartz Mountains, and at St. Blasien in the Black Forest, successful institutions are conducted.

At Vienna Prof. Schrötter has made great efforts to have an institution established, and, with very liberal help on the part of Baron Rothschild, who has offered lands and money, his plans will be carried out. At Munich, Lübeck, Hanover, and Stettin similar institutions are being planned.

Much of the encouragement toward action on the part of municipalities has come from the remark-

[1] In the report of a case of "unilateral absolute iridoplegia," soon to be published, it will be necessary to review the different theories concerning the manner of the origin of the roots of the oculomotor nerve.

[2] Read at the meeting of the American Climatological Association, held at Hot Springs, Va., June 13, 1895.

able success in the treatment of tuberculosis that has been obtained in private hospitals. Brehmer, who established his sanitarium at Görbersdorf, in Silesia, in 1854, reported after the first fifteen years that twenty per cent. of his 958 tuberculous patients had been permanently cured. Charles Theodore Williams recently stated that of 247 patients, chiefly in the early stages of the disease, who had been sent to his private Alpine Sanitaria, chiefly Davos, St. Moritz, and Arosa, "a cure was effected in 101, or 40.89 per cent.; great improvement in 73, or 29.55 per cent."

Dr. Trudeau in the last annual report of the Adirondack Cottage Sanitarium, which has just completed its tenth year of existence, states that from 20 to 25 per cent. of the patients have been apparently cured after a prolonged residence; cases in which the rational signs of pulmonary tuberculosis and the bacilli in the expectoration have been absent for three months or more, or in which there is no expectoration at all; any abnormal physical signs remaining being interpreted as indicative of a healed lesion. This, I may say, is still the only institution in this country that is strictly built on the cottage-plan. Two new buildings have been erected during the past year. The sanitarium has now twenty-two buildings, with accommodations for eighty-four patients. It has a free-bed fund of $14,000, through which it gives aid to the very poor, and an additional $25,000 has been put aside toward a permanent endowment-fund.

The new sanitarium at Paul Smith's in the Adirondacks, at an elevation of 1800 feet, is nearly ready for the reception of patients. This institution is called the Sanitarium Gabriels, and will accommodate fifty persons. It will be under the care of the Sisters of Mercy of the Roman Catholic Diocese of Ogdensburg, but is intended to be nonsectarian as regards the admission of patients. Dr. W. Seward Webb and Paul Smith have given 100 acres of land for a site. An infirmary, an administration-building, and a half-dozen cottages are included in the plans. The first will be a handsome structure, two stories in height and built of wood and stone, with a glass-enclosed solarium and arrangements for the open-air method of treatment. A nominal charge will be made for treatment.

A recent movement in New York City to erect a memorial to the late Dr. Alfred L. Loomis, a former President of the American Climatological Association, has met with a liberal response. Already one gentleman has contributed sixty-five thousand dollars toward the proposed sanitarium for tuberculous persons now being erected at Liberty, Sullivan County, New York, in memory of our lamented friend. The plan includes a central building, with a number of surrounding cottages; two of these at a cost of from three-thousand to five-thousand dollars apiece are being constructed. The elevation is two-thousand feet, and is reached by rail in five hours from New York City.

New York has also a large institution, the Seton Hospital, for tuberculous patients, at Spuyten Duyvil, near the Harlem River. It has accommodations for three-hundred. The State of Massachusetts has recently appropriated $150,000 for a similar institution. Colorado has two such institutions: the Glockner Sanitarium, with a capacity of forty, and the Bellevue Sanitarium, with a capacity of twenty-five. The latter, however, is not open at present through lack of funds for maintenance.

The Pennsylvania Society for the Prevention of Tuberculosis was organized April 10, 1892. Its object is the prevention of tuberculosis, first, by promulgating the doctrine of the contagiousness of the disease; second, by instructing the public in the practical methods of avoidance and prevention; third, by visiting the tuberculous poor and supplying them with the necessary materials for protecting themselves against the disease, and instructing them in their use; fourth, by furnishing the tuberculous poor with hospital-treatment; fifth, by cooperating with Boards of Health in such measures as they may adopt for the prevention of the disease, etc.; sixth, by advocating the enactment of appropriate laws for the prevention of the disease. Efforts have been made by the Society to have tuberculosis placed upon the list of diseases returnable to the Philadelphia Board of Health, and to empower the Board to disinfect houses in which deaths from this disease have occurred. Such measures have been carried out in New York City for the past six months with success, and are now to be carried out in the city of Buffalo, N. Y., where the Department of Health is adopting energetic measures toward the prevention of tuberculosis. Since June 15, 1895, all cases of tuberculosis occurring in the practice of any physician in the city must be reported to the department. On receipt of such notice a circular of information will be sent to the families and those in charge of the patient, giving strict rules as to sanitation, etc. Recognizing that the consumption of meat and milk from tuberculous animals is one of the frequent sources and modes of tuberculous infection of the human being, especially of bottle-fed infants and children of tender age, the Society resolved to urge upon the Legislature of Pennsylvania the necessity of the early enactment of laws to secure the exclusion of the meat and milk of tuberculous animals from this Commonwealth. Under these laws about 500 living cattle and a large number of fresh carcasses have been condemned as unfit for the dairy and the market.

Commencing with June 1, 1895, a new law, estab-

lishing a State Live-stock Sanitary Board, went into effect. This Board is composed of the Governor, the Secretary of Agriculture, a Dairy and Food Commissioner, and the State Veterinarian. To administer this law an appropriation of $50,000 will be at the disposal of the Live-stock Sanitary Board during the next two years, for dealing with the various contagious and infectious diseases, and for the first time in the history of Pennsylvania there will be a conservative and systematic plan of dealing with these diseases.

It is interesting to note in this connection that the Royal Commission on Tuberculosis reported in April, 1895, to the British government the conclusions of its important investigations, namely, that it is satisfied that the cause of an appreciable part of tuberculosis in man is conveyed through his food—*i. e.*, the meat of tuberculous cattle. The Commissioners believe that the danger lies not only in diseased organs unremoved in the dressing, but also in conveying to healthy parts tuberculous matter by means of the knives and clothes used by the butchers in dressing.

The Society for the Prevention of Tuberculosis has widely distributed its tracts, namely, 50,000 of tract No. 1, entitled "How to Avoid Contracting Tuberculosis;" and 40,000 of the other, entitled "How Persons Suffering from Tuberculosis Can Avoid Giving the Disease to Others." A great interest has been taken in the Society by physicians in all parts of the world. Boards of Health in almost every State in the Union have made application for these tracts, and have been supplied. Within a few weeks a request from Boston for 500 tracts was received, and very gladly complied with. Physicians in all parts of the South and West, in various portions of Canada, and even so far as the Hawaiian Islands, have made application for them.

Vigorous efforts were made during the past winter to secure the establishment in Philadelphia of a Municipal Hospital for the tuberculous poor. A committee of the Society also visited Harrisburg to urge the necessary State legislation to establish a State Sanitarium for tuberculous persons, to be located at a favorable elevation in the mountainous portion of the State. As a result of this visit the State Board of Public Charities of Pennsylvania recommended to the Legislature an appropriation of $50,000 to carry out the provisions of the bill. While these measures have not yet been successful, there is good reason to believe that the State will take the matter up as soon as some other important charitable measures, as, for instance, the new school for feeble-minded children in Western Pennsylvania and the new hospital for the epileptic insane, are accomplished.

The Society meets annually on the first Friday in May. Any person who pays one dollar or more into the treasury of the Society will be enrolled as a member for the year in which such payment is made. The by-laws provide that all money in the treasury, beyond that which is necessary for defraying the general expenses until the next meeting of the Board, shall be set aside for the use of a Hospital Fund. When the money in the Hospital Fund shall amount to $150 or more a tuberculosis patient shall be placed in a hospital for every $150 in the Fund.

There is no doubting that, as a result of the influence of this Society, of the American Climatological Association and of kindred organizations, and the issuing of so many thousands of tracts disseminating the principles of the communicability of tuberculosis and the best means of preventing it, the people of the United States are beginning to take very much more interest in the tuberculous patient personally, and that they see the necessity of organized effort to lower the mortality and eventually stamp out the disease. The city of Philadelphia, at least, is showing a marked response to the efforts made to lower the death-rate from tuberculosis. In this city, notwithstanding its growth in population, the actual number of deaths from pulmonary tuberculosis has gradually diminished since 1880. There were in each 100,000 of population 342 deaths from this cause in 1870, 317 in 1880, 264 in 1890, and only 220 in 1894.

We cannot tell in the State of Pennsylvania just how the mortality is tending, owing to our deficient system of registration; but we know that in Philadelphia there are about 6000 sick with tuberculosis, and in the State at large about 20,000 have the disease. In New York State the ratio of deaths from tuberculosis to the total deaths has steadily fallen since 1890. These facts are significant of the change that has come over the profession in the manner of looking at the disease and of treating it, and also of the attitude of the public itself, which is rousing from its long indifference. The people need plain teaching on this point, for most of them cling to the traditional idea that tuberculosis is strictly an hereditary disease, and consequently unpreventable. The large majority of people do not yet believe that it is contagious, and although, when requested, some persons may observe some of the sanitary precautions we advise, they do it often in a perfunctory manner. The other members of the family, who frequently take little account of the idea of the contagiousness of tuberculosis, do not co-operate in carrying out these measures. Greater efforts must therefore be made to reach the people.

More societies for the prevention of tuberculosis should be organized. We need to organize and maintain special hospitals and cottage sanitaria for tuberculosis. The first step is to find out the localities where medical measures will receive the greatest

aid from natural resources, from air and altitude and sunlight. The patient who is weakened in body, deprived of his usual means of livelihood, face to face with a long illness, with little to supply for himself or his family the necessaries of life, not to speak of other needs relating to his disease, needs special help, and it is no wonder that little can be done in our cities to stay the course of this disease. The best solution of the problem, I believe, will be to take these afflicted beings out of cities to brighter skies and evergreen forests, where Nature and art, hand in hand, may work together for their good, and, it may be, for their final cure.

CLINICAL MEMORANDUM.

INVERSION OF THE UTERUS.

By G. A. HIMMELSBACH, M.D.,
OF BUFFALO, N. Y.;
CLINICAL INSTRUCTOR IN MEDICINE, UNIVERSITY OF BUFFALO; ASSISTANT VISITING PHYSICIAN, BUFFALO GENERAL HOSPITAL.

The report of a case of inversion of the uterus by Crouse, in The Medical News, June 8, 1895, suggests to my mind a case that came under my observation in March, 1894. The patient, aged seventy-two years, a German, was brought to the Buffalo General Hospital. The ambulance-surgeon reported that he had found the woman in a most deplorable and filthy condition, in a small, ill-kept cottage, where she had lived a secluded life for fourteen years. The neighbors said that she would only make her appearance at long intervals, when forced to go out for provisions. She was a widow, with grown and married children, the youngest forty-one years old, and who were unable to live with her, owing to her eccentricities.

Upon entrance it was observed that the woman was evidently demented; she could not give a clear history of herself and not even of recent occurrences. In giving her her initial bath the nurse discovered a large tumor protruding from the vaginal outlet. My attention was called to the fact and a careful examination was made. I found a tumor the size of a large cocoanut in the position stated. It was covered with thick, dirty crusts or scabs, showing evidence of former ulceration and Nature's effort at healing, and presented a few circumscribed ulcerating areas varying in size from a dime to a silver quarter-dollar. The last were moist, sloughing, and foul-smelling, showing the very worst evidence of gross neglect. The remainder of the surface was covered with dry scales. Surrounding the circumference of this tumor was a thickened, pigmented ring, which appeared to be the former site of the cervix. Upon advice of Drs. Hopkins and Cary I anesthetized the patient, and after thoroughly cleansing the surface formed the fingers and thumb of my left hand into a cone and applied them to the most dependent part (the fundus), with the right hand in the suprapubic region. The parts were now entirely relaxed, and by careful manipulation the tumor was restored to the interior of the abdomen. Then the condition was found to have been one of complete inversion of the uterus and vagina. When replaced to their normal position the parts were so relaxed and so roomy that, with my fist clenched *in utero*, my whole forearm within an inch or two of the elbow was within the vulval opening. A most peculiar sensation was conveyed to my hand by the dry, wrinkled endometrium, which had for so long a time been the much-stretched external covering of the tumor. The hand was gradually withdrawn and large tampons were packed within the uterine cavity, to give to it bulkiness and to prevent its coming down again. Gradually these tampons were removed, and the uterus never again made its appearance externally during her three weeks' stay at the hospital. During the last week or ten days of this period the patient sat up and walked about the ward.

A few features of the case are interesting:

First, the perverted mental condition markedly present upon the woman's entrance entirely cleared up, and when discharged she conversed freely in her native tongue, showing no evidence of any perversion; but she could never give a clear history of her health for a few years prior to her coming to the hospital.

Second, a most interesting point was that on the second day following the restoration of the uterus the woman began to pass vesical calculi, and for two days afterward she passed in all twenty-four, varying in shape and ranging in size from a small split pea to a large white bean; many were facetted. They were made up of uric acid with a phosphatic crust. These were in all probability formed in the sacculated portion of the bladder caused by the dragging down of the soft parts, this sacculation becoming more or less obliterated when the tumor was replaced.

Third, it would seem hardly credible that with the amount of stretching and relaxation of the soft parts operative interference in the way of shortening ligaments was not called for, and that simple tamponade was sufficient.

MEDICAL PROGRESS.

Acute Nephritis due to Eczema.—Bruhns (*Berliner klinische Wochenschrift*, 1895, No. 28, p. 606) has reported seven cases of eczema, presenting also acute nephritis, in six of which it is believed that this developed with certainty as a sequela, while in the remaining one there was some doubt. In three of the cases no treatment to which could be ascribed the renal lesion had been employed prior to the onset of the albuminuria. In the fourth case diachylon-ointment had been employed, but this could with certainty be excluded as a cause of the nephritis, as no other symptoms of lead-intoxication were present and the amount used was inconsiderable; besides the renal symptoms only appeared four weeks after the beginning of the treatment. In the fifth case a tarry ointment and in the sixth case one containing styrax were used, and it is unlikely that either of these would be responsible for the nephritis. In the sixth case styrax was at first used and later balsam of Peru. In the seventh case a nephritis in the process of recovery was found, and this is included among the number on account of its similarity to the other cases.

Cerebro-spinal Meningitis in an Infant Six Days Old.—Rotch (*Archives of Pediatrics*, vol. xii, No. 8, p. 585) has reported the case of an infant, weighing 8¾ pounds at birth, and apparently healthy until the sixth day,

when it refused to nurse and vomited the little that it took. It cried out when asleep and at times would awaken with a sudden start. The temperature was elevated. On the following two days the infant had in irregular succession convulsions to the number of fifty, in the intervals of which it seemed perfectly well. The contractions were clonic and general in character and death took place in one. Upon post-mortem examination the inner surface of the dura mater appeared covered with opaque yellowish patches, the lymph being specially marked over the base of the skull. The vessels of the pia were markedly injected, and the meshes of this membrane were filled with an opaque, greenish-yellow purulent exudation, extending over the entire brain and into the spinal canal. Microscopic examination disclosed the presence of pneumococci.

Inoculation of Tuberculosis through Tattooing.—COLLINGS (*British Medical Journal*, No. 1795, p. 1200) has reported three cases in which local tuberculosis developed as the result of tattooing by a tuberculous person, who used Indian-ink rubbed up with saliva in the palm of his hand. The tuberculosis was conveyed by a lad, fifteen years old, who subsequently died of advanced pulmonary tuberculosis. A short time before his death he tattooed two of his brothers, aged thirteen and ten years, respectively, and a friend, aged fifteen years. The arms at the site of inoculation presented pustules and scabs. In all three cases there was enlargement of the epicondylar and axillary glands. The general health of the boys did not suffer appreciably. The lesions were all seen by Mr. Jonathan Hutchinson, who expressed the opinion that they were due to the inoculation of tubercle. A piece of skin from the arm of one was examined and presented well-marked giant-cells in the corium, but tubercle-bacilli could not be demonstrated.

Return of the Tendon-reflexes in the Course of Locomotor Ataxia.—RAICHLINE (*Comptes Rendus Hebdomadaires des Séances de la Société de Biologie*, 1895, No. 23, p. 508) has reported a case of locomotor ataxia complicated by hemiplegia of cerebral origin, in which not only did secondary contractures develop, but also the tendon-reflexes returned. The deep reflexes of the upper extremity became exaggerated immediately after the onset of the hemiplegia, which involved the left side, was complete, and set in without prodromes, without loss of consciousness, and without involvement of speech. The patellar reflex upon the paralyzed side returned in the course of four months and became normal or nearly so. At the end of six months the tendon-reflexes had partially returned upon the unaffected side, notably those of the biceps, the triceps, and the supinator longus.

The Toxin and the Antitoxin of Cholera.—As the result of an experimental investigation, RANSOM (*Deutsche medicinische Wochenschrift*, 1895, No. 29, p. 457) has found that it is possible to obtain from cholera-cultures a fluid free from bacteria possessing specific toxic properties. The clinical manifestations induced by this fluid are similar to those resulting from the ingestion of living cholera-organisms. From this fluid it is possible to isolate a substance whose action is identical with that of the original fluid. Animals susceptible to cholera and treated with the cholera-toxin yield a serum that is antagonistic to the action of both the cholera-poison and the living cholera-organisms.

THERAPEUTIC NOTES.

The Treatment of Typhoid Fever with Cold Baths.—VOGL (*Blätter für klin. Hydrotherapie*, Jahrg. v, No. 6; *Berliner klin. Wochenschr.*, 1895, No. 29, p. 643) gives the following statistics bearing upon the treatment of typhoid fever with cold baths, based upon recent experiences.

Jürgensen (Tübingen) with expectant treatment had a mortality of 22.1 per cent.; with partial bath-treatment a mortality of 7.1 per cent.; with methodic bath-treatment a mortality of 1.8 per cent. Brand (Stettin) with methodic bath-treatment had a mortality of 3.5 per cent. Ratjen (Hamburg) with methodic bath-treatment had a mortality of 4 per cent. Drasche (Vienna) with methodic bath-treatment had a mortality of 9.3 per cent.

From France, where the cold-bath treatment was only adopted late, the following figures were obtained: Tripier and Bouveret (Lyons), before the institution of the cold-bath treatment, had a mortality of 25 per cent. and afterward a mortality of 7.5 per cent. Richard, among 38 cases treated by expectancy and baths, had a mortality of 10.2 per cent., and among 38 cases treated methodically with the cold bath a mortality of 5.2 per cent. Juhel-Renoy found with expectant treatment a mortality of 14.2 per cent.; with methodic bath-treatment a mortality of 7.3 per cent. (collective investigation); and had with methodic bath-treatment a mortality of 4.7 per cent. (personal observation).

The following American figures are cited: Kellogg (Philadelphia) before institution of the bath-treatment a mortality of 17 per cent.; after institution of the bath-treatment a mortality of 4.5 per cent. Elliot (Philadelphia) before institution of the bath-treatment a mortality of 24 per cent.; after institution of the bath-treatment a mortality of 6.5 per cent. Osler (Baltimore) before institution of the bath-treatment a mortality of 21.8 per cent.; after institution of the bath treatment a mortality of 7.4 per cent. Thompson (New York) before institution of the bath-treatment a mortality of 19 per cent.; after institution of the bath-treatment a mortality of 7 per cent.

In Munich, between the years 1841 and 1860, as the result of medicinal treatment, the mortality of typhoid fever was 21 per cent. From 1860 to 1875, with partly expectant and partly bath-treatment, the mortality was 15.2 per cent. From 1875 to 1881–82 with bath-treatment, partly combined, the mortality was 6.5 per cent.

In the Treatment of Alopecia Areata, SABOURAUD (*Corresp.-bl. f. Schw. Aerzte*, 1895, No. 15, p. 479) first applies a cantharidal plaster to the bald area. On the following morning the blister is incised, the epidermis removed, and the exposed corium painted with a solution of silver nitrate, 1 to 15. This method has been employed in about 100 cases with better and more rapid results than from other methods. The treatment is based upon the assumption that the disease is one of the integument and not of the hair.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 Walnut Street,
Philadelphia.

Subscription Price, including postage in U. S. and Canada.

Per Annum, in Advance $4.00
Single Copies 10
With The American Journal of the Medical Sciences, Per Annum . . . 7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Philadelphia.

SATURDAY, AUGUST 24, 1895.

INSTINCT AS A GUIDE IN HEALTH AND DISEASE.

One of the most interesting problems presented to the medical man is the question, How far is Nature to be trusted? It is universally admitted that without her assistance we can do nothing, and that in the main her impulses are in the right direction. But are they always so? How far may we encourage our patients to follow their appetites and desires? Popular opinion says, "not at all," and our practice in the past has certainly given some ground for the rule. Our attitude toward the likes and dislikes of our patients is generally believed to be that of the nursery-maid, who sent the eldest member of her flock to "find Tommy and Flossy, see what they're doing, and tell 'em they musn't." As a matter of fact, the position occupied by the medical profession to-day is totally different from this, and we think it high time that official statement were made to that effect.

What then is the true value of instinct as a guide? Instinct is the crystallized experience of thousands of generations—or, to vary the metaphor, it is the golden seed-wheat chosen of a million harvests, threshings, and winnowings. It ranks lower than reason, because less of individual volition or judgment enters into it; but as a guide it is far safer, and is a spring of action far more reliable and effective, and so far as it goes it has no superior. Our lifelong struggle to form "good habits" is, by accurate analysis, merely an effort to change rational preferences into instincts. The beauty, the accuracy, and the beneficence of the instincts of the lower forms of life have been the marvel and the admiration of every observer and philosopher. Out of a thousand instances we need merely suggest the architectural instincts of bees and ants, the migrations of birds and fishes, and the chrysalis-making of moths and butterflies. But it is calmly assumed that in our own species alone instincts have utterly lost their force and value. Our pride would not permit us to depend upon or even to recognize them, lest we should seem to admit our kinship to "mere brutes."

Fortunately for us, our instincts still remain with us, in spite of our haughty refusal to recognize them officially, and control two-thirds of our actions; and it would be to our credit and benefit in every way if they controlled the majority of the remainder. Every time we neglect them we suffer. It is, of course, unnecessary to say that the great mass of our most important vital movements, such as breathing, swallowing, suckling, eating, drinking, walking, etc., would be impossible without instinct; but beyond all this, whenever we can find an instinct to follow, it is, nine times out of ten, safe to do so, even under civilized conditions.

Every physician must know that if civilized man would only follow his instincts in respect to fresh air, sunlight, exercise, food, water, bathing, etc., he would be far healthier, happier, and even more moral than he now is. Our dyspeptic race would be better in every way for a greater indulgence in "the pleasures of the table" (including *at least* twenty-two minutes for dinner), for more cat-like basking in the sun, for a good deal more "barbaric indolence," for more rebellion against the fiendish old saw that "Satan finds some mischief still for idle hands to do," for a more frequent giving way to the impulse to fling the yardstick out of the window and the ledger under the desk, and away to the woods, the fields, and the mountains! If the grown man would but run away and "go swimmin'," as the boy does!

An excellent illustration is the case of intoxicants and narcotics. Did any one ever hear of a baby

with an instinct for whisky or a child that enjoyed the taste of tobacco or the smell of a cigar? Tongue, nose, and stomach unite in their disapproval of all three, as the comic horrors of a boy's first smoke and the racking headache of the freshman's spree abundantly testify. It is only by systematic and repeated repression of instinct by "reason" and "higher intelligence" that these or cognate habits form; yet we have the colossal impudence to say that a man who is reeling drunk has "made a beast of himself." This is by no means an exceptional instance; indeed, it would hardly be too extreme to say that a large proportion of the diseases of civilization are due to the neglect or deliberate repression of some instinct.

However valuable instincts may admittedly be in health, the almost universal impression in both popular and professional circles is that they are just the reverse in disease. The sick man is popularly supposed to want just those things he should not have, and to dislike those things that are "good for him."

Indeed, altogether too much of both household and professional medical treatment was originally constructed on that very principle. Its chief reliance was placed upon "bitters" of all kinds, blisterings, bleeding, starving, etc.; in fact, the more disagreeable the drug or process, the more violent its effects, the greater its curative power was supposed to be. Even at this day a "medicine" must usually be bitter or it isn't much thought of by the laity, and a "hygienic dietary" is commonly constructed simply by forbidding everything that the invalid has any desire for.

The simple truth of the matter, unflattering as it may be to our professional pride, is that even up to the middle of the present century the old demon-theory of disease had far too much influence upon our therapeutics. Disease was still regarded as an entirety that must be driven out of the body of the patient by more or less violent or repulsive means. This distrust of the instincts in disease is not medical, but priestly. The wonderful "progress of modern medicine" has consisted very largely in getting rid of this idea. Wounds, for instance, instead of being poured full of wine, or oil, or turpentine, or other irritating substances, or burned with hot irons, or kept gaping for weeks, "to establish suppuration," or dressed with earth, cobwebs, pitch, or even excrement, are now simply thoroughly cleansed, closed as accurately as possible, and protected by the softest and lightest of dressings. In short, we simply follow our natural impulses, imitate the lower animals, and the result is that our mortality-rate after both accidents and operations is reduced more than 50 per cent.

In fever, for instance, the parched and gasping patient, instead of being swathed up to his neck in blankets, kept in carefully heated and darkened rooms, with doors and windows religiously closed, forbidden cold water, or, indeed, cool drinks of any kind, as if they were deadly poison, and systematically starved upon a "fever-regimen" of slops and washes of every description, is now-a-days placed between the coolest of sheets, and with the lightest of covering in cool, breezy, sunshiny rooms, is systematically fed with the most nourishing and digestible of foods, given water and fruit-juices freely, and not only bathed, but even put to soak in cold water.

Our most modern and most successful treatment of typhoid fever consists merely of a liberal milk-diet, encouraging the patient to drink at least a gallon of water a day, and plunging him into a cold bath whenever his temperature rises above a certain point. Again, we simply respond to the demands of poor, hot, thirsty Nature; and by so doing have lowered the death-rate from 16 per cent. to less than 5 per cent.

Even in morals the value of instinct as a guide is considerable, although there is here a certain amount of conflict between the individual or selfish instincts and the social or altruistic ones. While it is true that the interests of our vital desires or appetites are often so great as to cause us to disregard the rights of others in their gratification and thus violate our high or social instincts—"to sin," in theologic language—yet it is also true, as beautifully pointed out by Darwin, that the former are essentially temporary in their range and capable of but feeble recollection. The latter, on the other hand, are absolutely ceaseless in their action, and produce by their violation most lasting and powerful sensations, such as shame, remorse, loss of self-respect, feeling of isolation, etc., which become even more vivid with each successive recollection. In fact, the higher instincts, though at the time feebler, are in the long run more than a match for the lower. It would, indeed, be strange if the instincts that have *created* morals were not still to be trusted in their further extensions and outworkings.

EDITORIAL COMMENTS.

The Influence of Medical Libraries on Medical Literature.—All experiments on human beings are likely to produce unpredicted results. We venture, however, a prophecy: If the movement to introduce the study of medical literature into the medical course should succeed, each medical school would have its library, in which each student would be required to work at daily tasks. In a short time the result would be a critical literary spirit in the medical profession. If medical students learned as much of medical literature as students of biology now learn of the literature of biology, many medical works would have a diminished sale, and other works would have an increased sale in spite of a large cost-price. The trash that now forms a great part of the periodic literature would be excluded on the protest of the readers; or, it may be, only those journals would be patronized that furnished valuable medical thought in good form.

Some publishers may be so short-sighted as to think that every book that they put into a medical-college library will diminish many-fold that book's sale. This can only be the case when the book is unworthy. The college-library, in conjunction with the study of medical literature in the college-course, would increase the sale of the best medical literature, and, it is to be hoped, would diminish in some degree the sale of books of low degree now being so persistently exploited upon the medical profession. The systems and text-books of the commercial doctors and cheap publishers are debauching now the taste of the profession. Some radical means must be taken to counteract this influence. The study of medical literature in the medical schools is a promising educational advance, and a powerful adjunct to a better professional life. No other means of study gives so much interest to medical and surgical investigation. The broad outlook on life, and on professional life especially, that every young medical man should possess, is best inculcated by a study of the inheritance transmitted through our literature.

Those publishers would be short-sighted, indeed, who would not encourage this departure in medical education, so well adapted to magnify all that is good in their business. Those medical men who are now encouraging by their labors and their wealth the advancement of education in other directions can do their own profession a service by helping on this movement.

The Economic Advantages of the Metric System.—A select committee of the House of Commons, composed of seventeen members, held fourteen sessions, and after careful examination of many witnesses, and despite the proverbial dislike of Englishmen to change, all but one member voted to report that the metric system should be at once made legal, and within two years compulsory. The committee recites the economic disadvantages of the English system of weights and measures, and goes on to say that "not only is foreign trade in every branch seriously handicapped, but that the home-trade would be benefited by the adoption of more simple and uniform standards. . . One year's school-time would be saved if the metric system were taught in place of that now in use." From this judicious and judicial statement we may easily calculate one item of the cost of keeping up the antiquated and clumsy system of our weights and measures. If in every life one year's time is lost, and if we have forty-million of adults in our population, we are wasting thirty or forty million years every forty years, or a million years a year. As the average length of life is about forty years, this is equivalent to an annual expense of 25,000 lives. This looks laughable, but is there any hitch in the logic? If we lost 25,000 lives a year by cholera, what a hullabaloo would be raised! This is besides the commercial losses from trade, and also does not include the teachers' salaries! In medicine and science generally the expense is incalculable. The time wasted by one-hundred-thousand physicians in calculating the dosage and in writing prescriptions with our absurd grains, scruples, drams, ounces, pints, drops, and spoonfuls, would permit us to go to bed earlier every night or take a vacation each summer.

The Causes of Death in Coroners' Reports.—The report of the Coroner of the city of Philadelphia for the year 1894, as published in the report of the Bureau of Health, shows that 2231 inquests were held by that official during the year. The causes of death are given in 1181 cases, and then the statement is made that "other causes" were responsible for 1050 deaths! We have not been able to find in any text-book or encyclopedia at our disposal any reference to "other causes" as a factor in producing death. That this condition should be so mortal as to be responsible for nearly one-half of the deaths in the Coroner's cases, and yet be unrecognized by the medical profession, is quite startling. The unknown causes number a little more than one-hundred. The known causes include heart-disease, apoplexy, pneumonia, alcoholism, accidents of various kinds, suicide, and homicide. Now what other violent or sudden deaths are contained in the general term "other causes" we are at loss to understand. In Chicago and Brooklyn, it is rumored that railroads and other corporations find it advantageous to report fatal accidents as deaths from "other causes," although they often use such convenient phrases as "shock" and "concussion" in the death-certificates. In previous reports of the Coroner "other causes" has likewise figured as being responsible for from 40 to 50 per cent. of deaths coming under his notice.

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.

Sixty third Annual Meeting, held at London, July 30 and 31, August 1 and 2, 1895.

(Concluded from page 194.)

FOURTH DAY—AUGUST 2D.

DR. EDWARD ALBERT SCHÄFER delivered the Address in Physiology, which was entitled

ON INTERNAL SECRETION.

He pointed out that a secreting organ separates certain materials from the blood, and pours them out again—usually after effecting a change of some sort in them—upon external surfaces, or at least upon surfaces that are connected with the exterior. These form the secretions

that are most commonly known under that name. On the other hand, some secreted materials are not poured out upon an external surface at all, but are returned to the blood. These may be termed internal secretions, and they may be and are of no less importance than the better known and more fully studied ordinary or external secretions. The name of gland is the one that is usually applied to a secreting organ; and to those that furnish only internal secretions the name "ductless gland" has been applied. It is not, however, the ductless glands alone that possess the property of furnishing internal secretions. Every part of the body does, in fact, take up materials from the blood, and does transform these into other materials. Having thus transformed them they are ultimately returned into the circulating fluid, and in that sense every tissue and organ of the body furnishes an internal secretion. Moreover, certain important glands, which are provided with ducts, possess not only the faculty of yielding an external secretion, but have equally important, if not even more important, functions in connection with internal secretion. Thus both the liver and the pancreas are more essential to life, by virtue of the internal secretions that they furnish to the blood, than by their better known external secretions. The entire removal of either of these organs causes death, and this is due to the removal of the influences that they exert on the metabolism of the body by the loss of their internal secretions, and not to the cutting off of their external secretions. In the case of the liver it is well known that the bile may be diverted by a fistulous opening without any serious interference with the vital functions; and the same is the case for the pancreatic juice. The kidney is another instance.

The same result is not obtained with all glands. The salivary glands may be entirely removed without any marked symptom supervening. This is also well known to be the case with the mammary glands. On the other hand, removal of the generative glands leads to marked alterations in the development of other parts of the body. In the last-mentioned case the changes are probably produced through the nervous system, and are not connected with the internal secretion of the glands; and with respect to the salivary and mammary glands, we may assume that although they yield an internal secretion of some sort to the blood, it is of the same nature as that yielded by other organs, and that such other organs may act vicariously for those removed. This is, however, inapplicable to the liver, the kidney, or the pancreas; removal of which or restriction of their internal secretions is inevitably followed by a fatal result.

The liver affords an excellent illustration of the fact that internal secretions may, like ordinary or external secretions, either serve some useful purposes in the body (secretions proper) or may be formed only to be got rid of (excretions). The formation of sugar is an example of a useful internal secretion; that of urea of what would be termed in the ordinary sense an excretion, although urea is not actually got rid of by the liver, but is produced by that organ, to be got rid of by the kidney.

Among the racemose secreting glands the pancreas offers a characteristic peculiarity of structure. Besides the secreting alveoli and ducts, the pancreas possesses a peculiar epithelium-like tissue which occurs in isolated patches throughout the organ, and which is characterized by its extreme vascularity. We know of no other externally secreting gland that contains such islands of epithelioid tissue.

It was formerly believed that the sole function of the pancreas was to yield pancreatic juice, and this is in itself a sufficiently important function, seeing that this fluid contains ferments which act on all the principal organic constituents of the food. It had indeed been remarked that cases of glycosuria occurring in the human subject were frequently associated with disease of some kind of the pancreas. Frerichs found that 20 per cent. of the total number of cases of diabetes that came under his notice were accompanied by obvious changes in the pancreas. Rokitansky found in 13 out of 30 cases that the pancreas "was strikingly small, hard and bloodless; and in many cases it has been found so shrunken and altered as to be hardly recognizable save by its connections" (Silver). Claude Bernard had attempted as long ago as 1855 to remove the pancreas entirely, but all his attempts were unsuccessful, in so far that the animals speedily succumbed. In 1889, however, the operation was successfully performed by von Mering and Minkowski. They found that in all cases in which the entire pancreas was removed the operation was followed within the space of a very few hours by the appearance of sugar in the urine, and this to a great extent—as much as from 5 to 10 per cent. being found even in fasting animals.

Accompanying the condition of glycosuria there is also produced polyuria; and these conditions occur even under a purely flesh diet, and are accompanied, as might be supposed, by rapid wasting, and followed within the space of fifteen days or less by death. This result is not due to the loss of pancreatic secretion, for the pancreatic juice may be diverted by a fistula, and the animal may remain in perfect health. Nor is it due to the loss of the secreting structure; for it has been found possible to destroy the secreting structure of the organ without the supervention of diabetes. This was done successfully by Schiff in 1872. Schiff's method, which was a repetition of experiments by Bernard, was the injection of paraffin into the duct of Wirsung. In Bernard's original experiments all the dogs operated upon speedily died; but this was probably due to accidental causes, and not to the actual destruction of the pancreatic tissue, for in Schiff's experiments the dogs survived and remained in perfect health. The fact that removal of the pancreas is followed by glycosuria was not at that time known, and the appearance of sugar in the urine was not therefore looked for by Schiff. But there can be no doubt of the absence of any severe form of diabetes, because the animals underwent no wasting.

Recently the experiment has been repeated by Hédon and by Thiroloix. Thiroloix found that, although the gland was reduced by the process of atrophy supervening on the injection to a mere rudiment, symptoms of diabetes do not occur. It is well known that if a portion of the pancreas be left—about one-quarter or rather more—no glycosuria appears. In the great majority of these cases the animals remain healthy, so that it is clear that a portion only of the gland can prevent the diabetic symptoms. Nor need the portion of gland that is left remain in its ordinary situation. A fragment of the gland either from the same or from another animal may, in fact, be grafted elsewhere into the peritoneal cavity or under the skin. Provided the grafting be successful, and the portion of the gland employed be of sufficient size,

removal of the pancreas is now no longer followed by the usual symptoms. The animal may remain, in fact, in perfect health. If, however, at any subsequent time the grafted portion of pancreas is removed, diabetes supervenes, and the animal dies within a short time, as after a primary removal. It has been shown that the grafting of a portion of pancreas, the secreting part of which had been destroyed by injection of paraffin along the ducts, is also efficacious in preventing the advent of diabetes after removal of the pancreas. It must therefore be assumed that the material, whatever it may be, which is furnished by the pancreas to the blood, and which prevents excessive formation of sugar in the blood and in the urine, must be formed by some other constituents of the gland than the secreting-cells; for there is every reason to believe that these cells are eventually completely destroyed after the ducts have been blocked in the manner described.

It is a question whether the gland which has been thus caused to atrophy still shows the interstitial vascular epithelium-like tissue referred to; but it is extremely probable, in fact almost certain, that this tissue does not participate in the atrophy of the secreting part of the gland, and it seems, therefore, fair to assume that the pancreas mainly owes its function as an internally secreting organ, at least so far as regards the prevention of diabetes, to this tissue, which is apparently peculiar to it among secreting-glands. Various theories have been put forward to account for the effect upon carbohydrate-metabolism of removing the pancreas. It is, however, still entirely unknown how the pancreas does actually act. The effects of grafting just described entirely negative the view that the result is due to interference with the ganglia and sympathetic nerves at the back of the abdomen, a supposition that was at one time brought forward to explain the diabetes resulting from removal. It has been stated by Valli that in dogs which have been rendered diabetic by removal of the pancreas injection of pancreatic emulsion into the blood causes a disappearance of the diabetic symptoms, and many instances have been recorded of diabetes in man which, it is stated, have been benefited by the exhibition by the mouth of raw pancreas. With regard, however, to these statements, it may be remarked that the danger of injecting emulsion of raw pancreas into the blood would be great, on account of the tendency that extracts of gland-cells have to produce intravascular clotting; and, so far as the treatment by feeding with raw pancreas goes, it has been found that in dogs with pancreatic diabetes the excretion of sugar is not decreased, but increased, by giving raw pancreas with the food, even although this be of an entirely proteid nature. The only fact that appears certain in connection with the manner in which the pancreas prevents excessive production of sugar within the body is that this effect must be produced by the formation of some material secreted internally by the gland, and probably by the interstitial vascular islets, and that this internally secreted material profoundly modifies the carbohydrate-metabolism of the tissues. That it does so by influencing hypothetic "sugar-centers" in the bulb, as has been conjectured, is for various reasons improbable.

The next internal secretion for consideration is that of the thyroid gland. The process of study is in one sense simpler in this case, as there is no external secretion. That the thyroid gland is a secreting-gland no one who studies its structure and its mode of development can well doubt; except that it is unprovided in the adult state with a duct, it has all the features of structure of secreting-glands. It is formed of alveoli which are lined by epithelial cells, and these cells have been observed to exhibit changes after treatment with pilocarpin in no way dissimilar to those changes that have been noticed under like circumstances in the cells of true secreting-glands. Further, we can observe the secreted material within the vesicles of the thyroid, in the form of the substance known as "colloid."

The gland is extremely vascular and very richly provided with nerves, and both bloodvessels and nerves come into very close relationship with the secreting-epithelium. The glandular structure of the thyroid is more obvious in young than in old animals, and as age advances the organ undergoes a gradual process of degeneration, so that in advanced age its normal glandular structure can only with difficulty be recognized. As long ago as 1856 Schiff showed that extirpation of the thyroid in dogs is invariably followed by a fatal result. This observation, important as it now seems, fell for many years into oblivion, and it was not until clinical observations had again pointed to the importance of the gland that Schiff's experiments were remembered. These observations may be said to have commenced with the discovery of the disease known as myxedema by Gull in 1874, although the connection of that disease with affections of the thyroid was first recognized by Ord in 1878—an observation that has since been abundantly confirmed. In 1882 J. and A. Reverdin described the symptoms following upon complete removal of the thyroid body for goiter, and they recognized these symptoms as identical with those of the disease that had been described under the name of myxedema; they accordingly termed the collection of symptoms "operative myxedema." The results of the Reverdins were speedily followed by those of Kocher, who described, in a large number of cases, similar symptoms as following entire removal of the thyroid in man. Kocher pointed out that the effects are most marked in young subjects, and that they may not occur at all or be little manifest as age advances. These observations led to a renewal of his former experiments by Schiff, who, in 1884, published the results of sixty thyroidectomies upon dogs, in all of which the result was speedily fatal, the operation being quickly followed by the supervention of symptoms—tremors, spasms, and convulsions—which seemed to point to a serious disarrangement in the nutrition of the central nervous system. Schiff also discovered the fact that symptoms are prevented by a previous graft of a portion of the gland beneath the skin or into the peritoneal cavity.

The subject now became one of general interest and was taken up actively by many experimenters. In England Horsley, by employing monkeys—which survive the operation, as a rule, considerably longer than dogs—discovered that the myxedematous condition which is so characteristic of the removal of the thyroid in man is also produced in animals. It was further found by Allard and by Ewald that no results are obtainable by thyroidectomy in birds, and most observers state that the same is the case with rodents and herbivora generally. The absence of the result in birds has never yet

been satisfactorily explained; but various attempts have been made to explain the frequent absence of result in herbivora. It may be either that a portion of the gland has been left behind, or that there existed in the particular cases in question accessory thyroids and parathyroids separated from the main body, and not removed in the operation. This is the explanation given by Gley of the negative results that usually attend thyroidectomy in rabbits. Gley states that if in these animals care be taken to remove the accessory structures as well, the usual symptoms supervene. Whether this is a sufficient explanation of the lack of result obtained by other observers remains yet to be proved.

The symptoms that follow thyroidectomy are of two classes—nervous and metabolic, although we are not able to say that the nervous symptoms are not produced by metabolic changes in the tissues of the nervous system; nor is it certain that the metabolic changes in the tissues are not consequent on alterations in the nervous system. The most characteristic nervous symptoms are those that have been already mentioned—muscular tremors, passing gradually into spasms, and finally into convulsive attacks. These cease on section of the nerves passing to the muscles. They are, therefore, of central origin; indeed it has been shown that the excitability of the cortex of the brain, and even of the lower centers, is materially modified in animals that have suffered thyroidectomy. The metabolic changes that occur are most obvious in the connective tissues, and especially in the integument. These tissues become edematous, but the edema is not of the ordinary character. The fluid contains a superabundance of mucin; the integument swells, but at the same time the surface becomes dry, and there is a tendency to the shedding of hairs and of the superficial epithelium. This mucinous change is followed, if the animal remains alive for a sufficient time, by atrophic changes.[1] The nervous affection that primarily results is usually accompanied by slight fever. Later on, this passes off and the temperature becomes reduced, even to some degrees below the normal. These effects of thyroidectomy can be entirely prevented by thyroid grafts, and can be temporarily prevented either by injection of thyroid juice under the skin or even by taking thyroid juice or raw thyroid by the mouth. Dr. G. R. Murray has described the case of one monkey in which, in consequence of the removal of the thyroid, all the symptoms of myxedema had appeared, which was completely cured by repeated subcutaneous doses of thyroid juice. He does not, however, state how long the animal was kept under observation after treatment, and whether the cure was permanent. It is, indeed, scarcely probable that the subcutaneous injection or the taking by the mouth of thyroid juice would be followed by more than a temporary removal of the symptoms. The effects of grafts, however, are to all intents and purposes permanent, and it has been found, as in the case of the pancreas, that removal of the graft which has maintained the health of the animal after extirpation of its own thyroid is speedily followed—as with primary removal of the organ—by the usual symptoms of thyroidectomy.

Various theories have been advanced to account for the effects of removal of the gland. H. Munk holds, or until lately held, that the effects of removal are entirely due to interference with adjoining nervous structures in the neck. But this, as in the similar theory propounded to account for the effects of extirpation of the pancreas, is absolutely negatived by the results of thyroid-grafting. Besides this theory, which must at once be dismissed, there are two others which may be regarded as disputing the ground between them. Of these the one may be called the theory of "autointoxication," and the other that of "internal secretion." The autointoxication-theory assumes that there is a certain toxic substance which is constantly tending to accumulate in the blood, and which it is the duty of the thyroid gland to render innocuous and to remove. According to this, the function of the thyroid would be primarily excretory. This view is supposed to be supported by the statement that in animals which are dying after removal of the thyroid the blood is toxic for other animals, and especially for those that have already had the thyroid removed, although this operation may have been performed only a short time previously, and before the symptoms of thyroidectomy have had time to develop. It is not stated what the probable nature of this substance is, or by what tissues it may be formed. The "internal-secretion" theory would explain the phenomena of extirpation as due to the absence of a secretion which is formed within the thyroid, and which is passed into the blood, possibly through the medium of the lymphatics: a secretion which is necessary for certain of the metabolic processes within the body, and especially for those connected with the nutrition of the central nervous system and of the connective tissues. In the first place, beneficial and not toxic effects follow the exhibition of thyroid juice both in cases of thyroidectomy in animals and in myexedema and other affections in man. Secondly, extract of thyroid gland, whether prepared with water or glycerol and whether previously boiled or not, produces a distinct action upon the blood-vessels, so that the blood-pressure markedly falls, although the beats of the heart remain at about the same rate and of the same strength. This lowering of the blood-pressure without influencing the action of the heart can only be produced in one way, namely, by increasing the caliber of the arteries. Before this effect upon the blood-pressure was discovered it had been shown that the exhibition of thyroid juice or other preparations of thyroid in the human subject has a tendency to increase the caliber of the radial artery. It would seem, therefore, that the juice of the thyroid and extracts which are obtained from the gland have a distinct action upon the vascular system. Lorrain Smith found that in animals that have been deprived of the thyroid body the reaction to changes of temperature was abnormally rapid. When normal animals are exposed to a cold atmosphere the production of carbonic acid becomes increased consistently with the increased oxidation that is necessary to cause an increased production of heat, but this increase of carbonic acid does not take place immediately, but only comes on after a certain period of time, the temperature of the body being

[1] Semon has enunciated a theory to the effect that removal of the thyroid produces an interference with the full chemic development of the constituents of the connective tissues, so that these tend to take on an embryonic character, and it is well known that excess of mucin is characteristic of embryonic connective tissue.

in the meantime maintained normal by those physical changes which occur in the circulation, and which allow the quantity of blood brought to the skin, and the amount of heat thereby lost from the general surface of the body, to be varied. It is precisely these vasomotor changes that appear to be lacking after removal of the thyroid; for the production of carbonic acid becomes almost immediately increased by exposing thyroidectomied animals to a low temperature. That the thyroid gland yields an internal secretion which effects a useful purpose within the body appears to result conclusively from these facts, and the effects which follow thyroidectomy are probably due to the loss of that secretion. Whether the gland also possesses the function of destroying toxic products of metabolism that would otherwise tend to accumulate in the bood is a point that requires the production of more conclusive evidence before it can be regarded as established.

The next organ the internal secretion of which may be considered is the pituitary body. It is well known that the anterior lobe of the pituitary body is a structure that may in general terms be described as glandular, and although not in all respects resembling the thyroid there are nevertheless certain points both in connection with its mode of development and in the structure of the fully formed organ that might lead to the supposition that there is something functionally common to the two organs. So far as destruction of the pituitary body is concerned, experiments have given interesting results. The organ has been removed successfully in a number of cases in cats and in dogs. In all instances of complete removal death results, usually within a fortnight of the operation. The symptoms are (1) a diminution of the body-temperature, (2) anorexia and lassitude, (3) muscular twitchings and tremors, developing later into spasms, (4) dyspnea. Many of the symptoms show abatement after injection of pituitary extract. Vassale and Sacchi conclude that the pituitary must furnish an internal secretion which is useful in maintaining the nutrition of the nervous and muscular systems. Some of these symptoms, especially the muscular twitchings, are similar to those seen on removal of the thyroid. Moreover, it has been stated that after thyroidectomy the pituitary body becomes enlarged; and Rogowitsch has supposed that the fact that in rabbits thyroidectomy commonly fails to produce the usual results is due to the pituitary taking on a vicarious action, the pituitary being larger in proportion in the rabbit than in most animals.

Similar statements with regard to its enlargement have been made in cases of myxedema in which the pituitary has been examined. But, on the other hand, Schönemann, who examined the pituitary in a large number of cases of goiter, got no distinct evidence of its enlargement in that disease nor of any other marked change. And whereas enlargement and degeneration of the thyroid are accompanied by cretinism and myxedema, there appears to be a close connection between enlargement and degeneration of the pituitary body and an entirely different disease first described by Marie, namely, akromegaly, the most obvious symptoms of which are hypertrophy of the bones of the extremities and of the face, with some hypertrophy of the skin and mucous membranes, but without mucinoid degeneration. Moreover, the theory that the thyroid and pituitary may act vicariously appears to be entirely negatived by the physiologic effects produced by extract of the last-named gland. Tracings of the blood-pressure and heart-beats show that, whereas thyroid extract produces no obvious effect upon the contractions of the heart, decoction of the pituitary body causes great augmentation in the force of the heart's beat without, however, any accompanying acceleration of the rate. Further, the effect upon the arteries is precisely the reverse of that which is obtained by extract of thyroid. The blood-pressure rapidly rises, and that this rise is not due simply to augmentation of the heart's beats, but that it is also due to contraction of the arterioles, is sufficiently shown by the fact that if salt-solution containing pituitary extract be passed through the bloodvessels of a frog, the entire nervous system of which has been destroyed, the vessels markedly contract. This experiment conclusively shows that the effect upon the arteries is unquestionably a direct one, and in all probability this is the case also with the heart.

It may be fairly supposed, then, that the pituitary body also furnishes to the blood an internal secretion, and it would appear that this internal secretion tends to increase the contraction of the heart and arteries and to influence the nutrition of some of the tissues.

Lastly, the internal secretion of the suprarenal bodies may be considered. The immense importance of these glands in nutrition was indicated by Addison, who, in 1855, pointed out that the symptoms of the disease now known by his name are associated with pathologic alterations of the suprarenal capsules. This observation was tested experimentally by Brown-Séquard, who found (1856) that removal of the suprarenal bodies was rapidly and unfailingly fatal in all animals. The symptoms following the removal are practically those of Addison's disease, although much more acute. There are extreme muscular weakness and great loss of tone of the vascular system, with ultimately nervous symptoms, loss ot appetite, and other signs of general prostration. But the pigmentation that usually accompanies disease of those organs was not noticed by Brown-Séquard, and he inferred that this absence of pigmentation was probably due to the fact that a fatal result appears so rapidly after the complete removal of the capsules in animals that time is not afforded for the development of this symptom. This conjecture appears to have been confirmed by an experiment of F. and S. Marino-Zucco, who state that by inoculating the suprarenals of rabbits with pseudo-tubercle bacillus they have succeeded in obtaining not only the slow development of the ordinary symptoms of suprarenal removal, but also an augmentation in the pigmentation of the skin and hair. The experiment, however, requires confirmation.

It is needless to state that Brown-Séquard's results, following as they did upon Addison's observations, attracted much attention, and numerous investigators set to work to verify them. But many of these failed to confirm the results that were obtained by Brown-Séquard, probably by reason of the removal being incomplete or of the existence of accessory capsules; and after a few months of controversy the subject gradually dropped, and became for a long time almost forgotten. The interest in this subject has been, however, recently revived, and the experiments of Brown-Séquard have been repeated by various observers, including Brown-Séquard himself, Abelous and Langlois, Tizzoni, and many others.

Dr. Schäfer has himself made several experiments of the same kind on various animals (monkeys, dogs, cats, and guinea-pigs). All these observations have tended to confirm the original statements of Brown-Séquard. They show that animals deprived of their suprarenal capsules die rapidly, usually in the course of two or three days, with the symptoms noted, and the further fact is mentioned by Abelous and Langlois, and this is also confirmatory of a statement of Brown-Séquard, that the blood of animals dying in consequence of the removal of the suprarenal capsules is toxic for other animals which have recently been deprived of their capsules, although it causes no toxic results in normal animals.[1]

The symptoms caused by this blood are said by Abelous and Langlois to be those of curare-poisoning—paralysis, that is to say, of the intramuscular nerve-endings; and as the most marked phenomenon resulting from removal of the capsules is extreme muscular weakness, it has been concluded by them that after removal of these glands a certain toxic product of muscular metabolism accumulates in the blood, and that the function of the glands is to remove or destroy this toxic principle.

This is the "autointoxication"-theory of the suprarenal capsules, and is similar to that which has been applied to the thyroid body. Like the other autointoxication-theories it is chiefly founded upon the fact that the blood of animals which are moribund in consequence of the particular extirpation is toxic, especially for other animals that have been submitted to the operation. But is it not probable that the blood of an animal dying slowly as the result of any disease would be toxic to some extent, and that the toxic principles would more powerfully affect animals whose resisting power has been lessened by a recent severe operation? However this may be, whether the suprarenal capsules do or do not destroy a toxic principle which is formed elsewhere, and which would otherwise accumulate in the blood, they unquestionably produce a material that has properties entirely different from those stated to be possessed by the blood of animals deprived of their capsules. This material, which is probably the basis of the internal secretion of the glands, has most active physiologic properties, and to these attention will next be directed.

Experiments upon normal animals with extracts of suprarenal have been performed by a number of observers, but by all in a very incomplete manner. For the most part they have been satisfied to inject subcutaneously extracts made with water and other menstrua, and to observe the symptoms, if any, which result. As a matter of fact, in some animals that are so treated there are no obvious symptoms. The guinea-pig will stand a large subcutaneous dose of suprarenal extract without showing any symptoms at all, or with, perhaps, only a slight acceleration and increase of the force of the pulse. The same appears to be the case with the cat and the dog, unless a very large dose be injected. Rabbits, on the other hand, are extremely susceptible to the influence of suprarenal extracts. If a large dose be given, the animal may succumb within half an hour. If, on the other hand, the dose be only moderate in quantity, it may not show any symptoms at all for some hours, and then it may suddenly succumb. This primary absence of symptoms has been also noted by Foà and Pellacani in dogs, who state that in many of the animals which they experimented upon in this way there were no symptoms at all apparent upon the day upon which the injection was given, but that the next morning the animal was usually found dead.

The cause of death, it may be added, in this case is not by any means clear. Foà and Pellacani have supposed that it may be due to paralysis of the respiratory center, but the slight effect that intravenous injection of suprarenal extract produces upon this center does not lend support to this conjecture.

The physiologic effects of intravenous injection of suprarenal extract are far more striking. Experiments by Dr. George Oliver and Dr. Schäfer, performed during the last two years, show conclusively that the medulla of the suprarenal capsule contains a dialyzable organic principle, soluble in water, and not destroyed by boiling for a short time, which exerts a powerful physiologic action upon the muscular system in general, but especially upon the skeletal muscles, the muscular walls of the bloodvessels, and the muscular wall of the heart. A certain amount of action is also manifested upon some of the nerve-centers in the bulb, especially the cardio-inhibitory center, and to a small extent upon the respiratory center.

The effect upon the skeletal muscles is well shown in the frog, and can also be seen in mammals. The contraction of the muscle in response to a single excitation of its nerve is as ready as in the normal animal; but it is greatly prolonged, so that the result is comparable to that produced by a small dose of veratrin, which has the effect of enormously increasing the contraction resulting from a single stimulation of the muscle or its nerves. It is in no way comparable to a curare-effect, for the muscles remain as excitable through their nerves as before. It is, therefore, an effect entirely different from the so-called autointoxication-paralysis that is stated to result after removal of the suprarenal capsules in animals, and the material that is extracted by water, therefore, from the suprarenal capsules is certainly not the same material that is said to accumulate in the blood after the removal of those organs.

The action upon the circulatory system may be divided into the action upon the heart and the action upon the arterial system. Upon the heart the effect differs according as the vagi are cut or uncut. When the vagi are uncut, and the heart is therefore still in connection with the cardio-inhibitory center in the medulla oblongata, the action of suprarenal extract is to slow, and even to stop entirely, the contraction of the auricle. Under these circumstances the ventricle continues beating with an independent slow rhythm. The result is to cause the pulse to be very slow. On the other hand, when the vagi are cut or their cardiac ends paralyzed by

[1] It is stated by Brown-Séquard that injection of extract of suprarenal under the skin of animals, the suprarenal capsules of which have been removed, has a partial success in prolonging life. Dr. Schäfer knows of no cases in which animals in this condition have been kept alive for any length of time, either by injection in this way or by the taking of suprarenal by the mouth. Nor is he aware of any successful attempts that have as yet been made to effect a graft of the organ into another place, although there can be little doubt that if such a graft were to become successfully rooted, the result would be similar to that which is got with grafts of pancreas and of thyroid. It appears, moreover, to be true that some cases of Addison's disease are distinctly benefited by extract of suprarenal capsule, taken by the mouth.

atropin, the effect upon the heart is precisely the reverse. The strength and frequency of the auricular contractions are markedly increased, and those of the ventricle are correspondingly augmented. This naturally has the effect of sending a vastly greater amount of blood into the arteries, which by itself would alone produce a great rise in the arterial pressure. The direct action upon the arteries is, however, quite as marked as that upon the heart. If the blood-pressure be taken in a dog in the usual way by connecting a mercurial manometer with the femoral artery, and if a minute dose of suprarenal extract be now injected into a vein, it is found that even with the vagi uncut and the heart therefore slowed by the action of the extract the blood-pressure rises considerably. But with the vagi cut or paralyzed by atropin the rise can only be characterized as enormous.

The contraction of the arteries is further exemplified by the fact that if an organ such as a limb or the kidney or the spleen be enclosed within a plethysmograph, or oncometer, the instrument indicates an enormous diminution in volume of the organ, which can only be accounted for by a contraction of its arterioles. This contraction is produced by the direct action of the drug upon the muscular tissue of the smaller arteries, and not indirectly through the vasomotor center, for it obtains in the mammal equally well with the spinal cord cut or the bulb destroyed, or even in the case of the arm after the brachial plexus has been severed. In the frog it is produced also with the brain and spinal cord completely destroyed and salt-solution containing suprarenal extract allowed to flow through the arteries.

Under these circumstances the flow of fluid, which without the suprarenal extract may have been comparatively rapid, becomes almost completely stopped, and this can only be due to the direct action of the extractive substance upon the muscular tissue of the smaller arteries. After the vagi have been cut the blood-pressure may rise to four or five times its original height; no other known agent will produce such an enormous increase of pressure except direct stimulation of the vasomotor center. It is not the case, however, that this center is stimulated by the drug, for the action is essentially a peripheral one.

The effect passes off in the course of a few minutes. After a dose, no matter whether small or large, has been injected into a vein, and has produced the results noted, the bloodvessels slowly resume their ordinary caliber, the augmentation and increased frequency of the heart's beats become gradually lessened, and the blood-pressure recovers its normal condition. Whilst the pressure is raised under the action of suprarenal extract, there is apparently no possibility of inhibiting the arterial contraction; even the strongest stimulation of the depressor nerve, which under ordinary circumstances produces through the vasomotor center a marked dilatation of the arterioles, is without result during the activity of this extract. The question naturally arises, How is it that the effect so soon disappears? In what manner is the active principle eliminated? It is not eliminated by the kidneys, for the effect passes off just as quickly, even although the renal arteries are clamped. It is not eliminated by the suprarenals themselves, for the same fact holds good for the suprarenals. It passes off almost equally quickly if the aorta and vena cava are tied in the upper part of the abdomen, so that there is no circulation of blood whatever in the abdominal organs. It is not oxidized or otherwise destroyed by the blood, for it retains its full potency even after it has been twenty-four hours in contact with that fluid. The most probable explanation of the disappearance of the effect seems to be that the active principle becomes packed away, and eventually rendered innocuous in certain organs. That the muscles take most part in this storage is probable from the fact that the physiologic effects upon the skeletal muscles are manifested for a long time after the effects upon the heart and arteries have disappeared.

One of the most interesting and important facts regarding the material that is yielded by the suprarenals is the minuteness of the dose that is necessary to produce these results. As little as 0.0055 g. of dried suprarenal is sufficient to obtain a maximal effect upon the heart and arteries in a dog weighing 10 kilograms. For each kilogram of body-weight, therefore, all that is necessary to produce a maximal effect is 0.00055 g., or little more than half a milligram.

It has been shown that the active principle is contained only in the medulla of the gland, not in the cortex, and the medulla in all probability does not form more than one-fourth of the capsule by weight. Of the dried medulla certainly not less than nine-tenths is composed of proteid and other material which is not dialyzable, and which otherwise does not conform to the chemic properties that have been ascertained to belong to the active substance of the gland. So that, if these facts are taken into consideration, it is found that in order to produce a maximal effect a dose of not more than fourteen-millionths of a gram per kilogram of body-weight is all that is necessary. It is certainly true to say that one-fourteenth of this dose will produce some effect, although not perhaps a very large one. The astounding conclusion is thus arrived at that the active principle of the suprarenal capsules, taken in the proportion of not more than one-millionth part of a gram per kilogram of body-weight, which would be equivalent to $\frac{1}{15000}$ g., or less than $\frac{1}{6000}$ grain, for an adult man, is still sufficient to produce distinct physiologic results upon the heart and arteries.

It may be considered probable that the suprarenal capsules are continually secreting into the blood this active material which, although present in that fluid in only minute quantities, may yet be sufficient to produce an effect which is beneficial for the performance of the functions of muscular tissue, and especially the muscular tissues of the vascular system. It has, in fact, been stated that the blood of the suprarenal vein contains a sufficient amount of the active principle of suprarenal extract to produce marked physiologic effects. Dr. Schäfer has made three very careful experiments in an endeavor to confirm this statement, but he has not been able to find that the blood of the suprarenal vein does actually contain a sufficient amount of this material to produce, even in doses of as much as 10 c.cm., any more result than venous blood generally. But whether it can be shown, experimentally or not, there is very little doubt of the fact that the materials formed pass somehow or other into the blood; and, when the results of suprarenal injection are compared with the converse effects obtained from the removal of suprarenals and from disease of those organs, no other conclusion can

be reached than that we have here a notable instance of internal secretion.

The general results to which we are led from a consideration of these facts point very strongly in favor of the notion that internal secretions are yielded both by the ductless glands and by what are usually known as the true secreting-glands, and that such internal secretions may be of no less importance than the better recognized functions of the external secreting-glands. That failure of one or other of these internal secretions may occasionally have to be reckoned with by the physician there can be no doubt, while on the other hand the therapeutist will be able to avail himself of the active principles which the internally secreting organs afford, and in certain cases to use their extracts in place of the hitherto more commonly employed vegetable medicaments.

That the subject has a vast future there can be little hesitation in predicting, for, in spite of the advances that have been made in elucidating it during the last few years, very many points still remain obscure. Nevertheless, the way the physiologist has attempted to show may now safely be followed by the practitioner, and the results of these physiologic experiments, as well as clinical and pathologic observations in the same direction which are steadily accumulating, cannot fail to throw light upon and to assist in the diagnosis and treatment of many ill-understood symptoms of disease.

NEWS ITEMS.

The American Dermatological Association will hold its nineteenth annual meeting at the Windsor Hotel, Montreal, Canada, September 17, 18, and 19, 1895. The following program has been arranged: Address by the President, Dr. S. Sherwell. Angiokeratoma of the Scrotum; Raynaud's Disease of the Ears; Report of cases, by Dr. J. A. Fordyce. Two Cases of Hydroa Vacciniforme, by Dr. J. E. Graham. Two Cases of Bromid Eruption, by Dr. G. T. Jackson. The Value and Limits of Usefulness of Electrolysis in Dermatology, general discussion. Dermatological Notes, by Dr. W. A. Hardaway. The Epitrichial Layer of the Epidermis and its Relationship to Ichthyosis Congenita, by Dr. J. T. Bowen. Remarkable Drug-eruption, by Dr. F. J. Shepherd. A Hitherto Undescribed Sequel of Non-parasitic Sycosis, by Dr. J. A. Cantrell and Dr. J. F. Schamberg. The Infected Scratch and Its Relations to Impetigo and Ecthyma, by Dr. H. G. Klotz. A Contribution to the Study of Mycetoma, by Dr. J. N. Hyde. Unusual Papulo-pustular and Fungating Bromid of Potash Eruption in a Baby, by Dr. G. T. Elliot. An Etiological Puzzle, by Dr. J. C. White. Studies on Some Dermatological Subjects, by Dr. A. R. Robinson. A Unique Case of Agminate Folliculitis of Parasitic Origin, by Dr. M. B. Hartzell. Note on Antiparasitic Treatment of Eczema, by Dr. J. Zeisler. The Treatment of Erysipelas Based Upon a Second Series of Fifty Cases, by Dr. C. W. Allen. Notes on Drug-eruptions, by Dr. J. A. Fordyce. Sleep in Its Relation to Diseases of the Skin, by Dr. L. D. Bulkley. Exhibition of Photographs of Unusual Cases, by Dr. H. W. Stelwagon. (Title to be announced), by Dr. S. Lustgarten. Urticaria Pigmentosa. Case twenty years under observation, by Dr. P. A. Morrow. Note on the Elastic Circular Bandage, by Dr. G. H. Fox.

The Mississippi Valley Medical Association will hold its twenty-first annual meeting at Strassburg's Academy, Detroit, Michigan, September 3, 4, 5, and 6, 1895. In addition to the elaborate scientific program that has been prepared, generous provision has been made for social entertainment, and the meeting promises to be a most successful one. The usual reductions in railway-fares have been secured and ample hotel-accommodations provided for.

The Medical Examining Board of Virginia will begin its examination of candidates for licence to practise in Virginia, in Wytheville, promptly at 9 A.M., Tuesday, September 3, 1895. The Board itself will meet at 8 P.M., Monday, September 2d, for business. All letters with reference to this Board and the examinations should be addressed to the Secretary of the Board, Dr. Benjamin Harrison, Franklin and Seventh Streets, Richmond, Va.

Dr. Kurt Schimmelbusch, a rising young surgeon of Berlin, died August 2d, at the age of thirty-six years.

Dr. James W. H. Walker died August 20th, aged twenty-four years, while bathing at Wildwood Beach.

For the James E. Reeves Fund we have received from Fred Volz $1; Dr. N. W. Leighton, $2.

BY HENRY J. BERKLEY, M.D.,
OF BALTIMORE, MD.

THE interest that has recently been taken in the action of a number of soluble bacterial poisons produced in the course of certain infectious diseases, and capable of inducing various epiphenomena from their effect upon the nervous system, is well attested by numerous articles from the pens of authors in the four principal languages of the civilized world. The endeavor of the majority of these workers has been to discover in the corpus of the nerve-cell certain definite changes by means of selective stains, rather than to take up the several members of the neuron and consider them separately, and, indeed, this has only recently become possible.

While it is possibly stretching a point to consider blood-serum in the light of a bacterial poison, its action upon the tissues is not dissimilar, as may be seen from the results of the examination of other organs than the cerebrum from rabbits dying of chronic serum-poisoning, and it is highly probable that we shall eventually find in every person dying after the long-continued action of soluble poisons, whether bacterial or chemic, a class of lesions of the neuron similar to those described in this communication.

In the pathologic material from the autopsy-table we are sadly hampered by a multitude of post-mortem and other changes, which, though of great moment, are imperfectly known. Therefore, experimental material, under full control from the moment the inoculation is made, through the various stages of the experiment down to fixation and the staining and mounting of the sections, is of the utmost value in establishing a precedent for a similar class of lesions in the human being, especially as there are no wide anatomic differences between the nerve-cell of the animals used and those of man.

The material for the purposes of the study is at the present time small in amount but as it is for the moment impossible to add to it, and as the lesions in all the sections have been very constant, and of a well-defined though new type, I have concluded to utilize what I have on hand, and add to the results at a later date. I shall, therefore, confine myself to a description of the histologic changes found, without indulging in speculative conclusions, an intention for which apology is hardly needed.

It is to my mind proved by the destructive action of poisons on the nerve-cell of the cortex that it only requires the long-continued action of almost any soluble toxin to cause destructive effects on the neuron, and that these do not call for the presence of a micro-organism. This principle may be more clearly demonstrated in subsequent papers, and it will probably eventually be shown that poisons that are supposed to be limited in their action are probably universal nerve-poisons, and that their continued action results in an extensive degradation of the entire nervous system, if only a sufficient length of time be allowed them.

In the winter of 1893, Dr. Simon Flexner, of the Pathological Laboratory of John Hopkins Hospital, began a series of experiments upon the action upon rabbits of blood-serum obtained from man and the dog. These researches have been continued, although an outline of the pathologic changes found after the inoculations, in connection with a series of other studies, has already been published.[1]

Briefly, Flexner found that injections of serum of 1.5 per cent. of the bodily weight of the animal experimented upon were usually fatal, death occurring either immediately or after the lapse of ten or twelve hours. Quantities equal to 1 per cent. of the bodily weight caused profound disturbances, including hemoglobinuria and albuminuria, less commonly anuria, and in a few instances immediate death. When death followed at once it was usual to find thrombi in the right side of the heart, which now and then extended into the pulmonary artery and its branches. Cases in which the death of the animal was delayed for a time were of especial interest, as they showed well-marked lesions resembling in many ways the changes described in connection with the toxalbumins of diphtheria, ricin, and abrin.

The organs studied were the spleen, liver, kid-

[1] "The Pathologic Changes Caused by Certain So-called Toxalbumins." THE MEDICAL NEWS, Aug. 4, 1894, p. 116.

neys, and lymph-glands. In the acute cases the spleen showed a tolerably rich fragmentation of nuclei situated especially in the Malpighian bodies; the liver, certain foci of cellular necrosis; while the renal epithelium was degenerated and many casts blocked the kidney-tubules. Very extensive lesions were found in one animal that died on the thirteenth day. The microscopic appearances were those of chronic interstitial processes in the liver and kidney. In the latter organ the tubules were in places atrophied and surrounded by a new growth of connective tissue; in other places the tubules were dilated and their epithelial lining degenerated. In the liver the chronic changes were exceedingly well marked, and were an accurate reproduction of cirrhosis in the human being. Areas of newly formed or forming connective tissue proceeded from the portal spaces and from the capsule; newly formed bile-ducts were numerous, but what was of especial moment was the association with these changes of another process, viz., acute degenerative changes in the liver-substance, which were often distinctly the starting-places of the sclerosis. In the spleen masses of fibrous tissue were found. These changes show that the damage the serum is capable of doing is not limited to the corpuscular elements of the blood, for the tissue-cells also are not indifferent to its action.

From a later series of experiments than those just referred to, Dr. Flexner very kindly placed at my disposal the cerebra of several of the rabbits, in order to enable me to determine if the nerve-cells suffered from the action of the serum in a manner equivalent to those of the viscera mentioned. Unfortunately for our closer knowledge of the cerebral cells, these elements do not show mitotic figures, nuclear fragmentation, and coagulation-necrosis in the same manner as the liver-cells, but with our best stains, whether chemic combinations with the cellular substance or simple dyes, they are eminently stubborn to microscopic analysis; and from the reaction of the protoplasm to the dyes we can demonstrate in cells we perforce know must be diseased only indefinite alterations in the amount of absorption of the dye by the protoplasm, especially of the chromophilic particles, and most uncommonly any definite changes in the nucleus or nucleolus. These difficulties in obtaining accurate results from minor changes in the nerve-cell probably arise from the circumstance that the nerve-cells are completed elements, incapable of regeneration, and only show alterations of a pronouncedly degenerative type.

The material for this study has to this time been the brains of three rabbits from parts of two series of serum experiments, and, so far as the lesions of the cortical cells were determined, they were constant and identical in all the animals, though varying in intensity, seemingly according to the severity of the poisoning, as rabbit No. 2, first series *a*, which died from the result of an injection and not from the long-continued poisoning the others underwent, exhibited vastly larger numbers of normal cells than its companions in the investigation. It will be noticed in the table that this rabbit only lost about two-hundred grams in weight, and, accordingly, was not so greatly emaciated as the others. It is, at present, impossible to determine exactly what part the denutrition of the tissues plays in the production of the lesions of the nerve-cell, but I can hardly doubt that it is very secondary to the direct influence of the poison upon the cell, for in human alcoholics that show no emaciation the same kind of lesions are found, varying somewhat in intensity.

A synopsis of the histories of the rabbits comprising the basis of this study is given in the following table:

SERUM RABBIT SERIES.

Number	Age.	Weight at beginning of experiment.	Begun inoculations.	Quantity injected.	Frequency of inoculation.	Date of death.	Weight at death.	Clinical cause of death.	Gross anatomic lesions.	Remarks
1 Series 2, *b*.	Adult.	1700 g	Nov. 22 1894	6 c.cm. increased to 18 c cm.	Intervals of 2 w'ks.	Apr. 8 1895	1200 g.	Exhaustion.	Great emaciation; no visible lesions.	There were no well-marked meningeal changes in any of the rabbits.
2 Series 1, *a*.	Adult.	1700 g.	Nov. 6 1894	6 c.cm. increased to 18 c.cm.	Intervals of 2 w'ks.	May 5 1895	1500 g.	Overdose of serum.	Thrombi in heart and brain.	Injections of 12 c.cm. were fatal in control-rabbits.
3 Series 1, *b*.	Adult.	1700 g.	Nov. 6 1894	6 c.cm. increased to 18 c.cm.	Intervals of 2 w'ks.	May 31 1895	1300 g.	Exhaustion.	Great emaciation; no gross lesions.	Rabbit No. 2 died suddenly after an injection of serum.

METHODS OF PREPARATION AND STAINING.

The methods pursued in the preparation of the cerebral tissues for this investigation were similar to those made use of in Part I,[1] of these studies, namely, fixing the tissues in alcohol and in Müller's fluid, and after treatment with various anilins, hematoxylin, and silver-staining, according to the silver phospho-molybdate formula, as already given.

[1] Part I, "Experimental Lesions Produced by the Action of Absolute Ethyl-Alcohol on the Nerve-cells of the Rabbit's Brain," will appear in the autumn number of Brain.

The control-preparations were obtained from the cerebra of two young but full-grown rabbits, treated exactly according to the same formulæ for the fixing and staining, kept for the same length of time in the hardening media, and stained exactly by the same procedure as the serum-brains, often running the two together in the same jars.

As mentioned in the first section of these studies, there are upon the dendrons of the nerve-cells of the cortex a minimal number of thickenings or varicosities. The majority of these occur at the forkings of the dendritic branches, and rarely indeed is one to be found in the course of any of the finer branches in the normal brain. In the course of the axis-cylinder there are also knots of somewhat greater frequency, which begin at a variable interval from the cellular body, and continue through the entire intra-cortical course of the axon. Occasional varicosities of the dendron must, therefore, be held to be normal, the same holding good for the axon, although in the latter they are present in greater frequency. Since Coella, Greppin, Andriezen, and a few others have found in human brains, principally those of paralytic dements, an increased number of swellings upon the dendrons, the subject of these varicosities has attracted some little attention. Flatau[1] has quite recently discussed them at some length, and has arrived at the conclusion that they are natural.

It is quite possible to imagine that normal brains have a varying number of varicosities upon their dendrons, but when they increase vastly in size and occupy the whole dendron, they must be held to be abnormal, especially when they present a size that is incompatible with anything in the normal control-preparations; and the entire cell, with the exception of the axon, frequently shows evident signs of the presence of a destructive process. Not only are these abnormal swellings of great frequency on the finer branches and along the stems of the pyramidal nerve-cells, but it may readily be demonstrated that the very varicosities normally present, particularly the enlargements at the branchings of the dendrons, take on this alterative process, and in themselves became tumefied. Furthermore, we have one certain sign of dendritic degeneration in the pyramidal and some other nerve-cells that seems to have entirely escaped the attention, not only of the criticisers of the value of the probable degeneration, but also of its exponents. I refer to the disappearance of the gemmules or lateral buds upon the branches of the dendrites, which takes place whenever the tumefactive process is at all advanced, or even occurs coequally with this.

I have elsewhere written more fully of the gemmule and its significance histologically, and in certain forms of dementia, and it suffices now to give a short anatomic description of one very interesting part of certain of the most important of the nerve cells, which for some unexplained reason, possibly from defective staining, has hitherto received but little attention. The gemmule, in its most developed state, is found only on the dendrites of two classes of nerve-cells, the pyramidal or psychic cells of the cerebral cortex, and the Purkinje cells of the cerebellar cortex. Histologic differences in the appearance of the gemmules are very apparent in these two varieties of cells. With the pyramidal bodies they present very much the appearance of a thin pin with a rounded head, having its sharpened point stuck into the protoplasmic substance along the edges of the dendrons, both the ascending and basal of the cells. They are arranged with considerable regularity along the thicker protoplasmic branches, and at a rectangle with the stem of the dendrite.

On the finer dendrites the intervals between the gemmules are slightly increased, and while preserving the same form as on the thicker branches they are slightly longer, and have less of the rectangular disposition. On the branches of the Purkinje cell the gemmules are very numerous and much more closely set together than on those of the pyramidal cell, and they give to the neuron a furry appearance. Besides these inherent characteristics, they begin by a broad base, do not increase in size as they extend outward, and terminate not in a rounded knob, but in a flattened ending that is no larger than the proximal portion of the stem. Here and there between the others single ones are found, similar in appearance to those of the cortical cells.

The function of the gemmule probably is to receive nerve-impulses from the endings of the numerous terminal nerve-fibers that seem almost to touch them, and to carry these impressions to the dendrite, and by its medium on to the cell-body. Differences in the function of the gemmule of the pyramidal and Purkinje cell are probable.

Histology of the Alcohol-hardened Serum-Specimens.

The staining of the sections for this portion of the study was by Nissl's methylene-blue and magenta, and hematoxylin-eosin. The only noticeable difference between the several brains was that in No. 2 the perivascular spaces contained a considerable number of polynuclear leukocytes, while in the other specimens these corpuscular bodies were absent.

The larger and medium-sized arteries have absolutely no sign of alteration in their several coats. The intermediary vessels are not at all prominent; their sheaths are normal; and the perivascular

[1] Archiv für Mikroskop. Anatomine, May, 1895.

spaces, while distinct, are not dilated, and contain no foci of round cell aggregations and no hematoidin débris. The capillaries and veins are normal. The endothelium of the vessels shows no trace of swelling or other abnormality.

The staining of the nerve-elements by the Nissl methods was made as intense as possible, and the decoloration not allowed to proceed quite to the usual point, in order to leave the protoplasmic processes stained to their fullest extent. The nuclei of the nerve-cells do not seem to be shrunken or irregular in contour. Few of them are of other than the mono-nucleolar variety. This nucleolus is smooth, lies toward the center of the nuclear ring, and shows no alteration in its capability for the absorption of the anilin.

Changes in the protoplasm of the corpora of the cells are somewhat indefinite. The protoplasm takes the anilin stain well, but the chromophilic particles are not well defined, and the intervening spaces between them seem to be occupied with more of the fine granules than are present in the control-slides. No stress can be placed on these indefinite changes.

A very few of the pyramidal cells contain vacuoles, but not even as many as three in a section. Seldom is there any appreciable shrinkage in the protoplasmic body ascertainable. The protoplasmic arms of the cells are very finely granular. In some of them small knots are to be seen, the swelling being recognizable from the absorption of a greater quantity of the dye than is present in the portions more distant from and more proximal to the cell-body. In the swelling the fine granules become less distinct than elsewhere.

In the cerebellum there is nothing noticeable in the cells of the granular and molecular layers. A few of the Purkinje cells are vacuolated.

Histology of the Müller's Fluid-hardened Specimens.

The staining of these sections was solely by the silver phospho-molybdate method. Between Brains 1 and 3 there were no microscopic differences of moment. Brain No. 2 showed a slighter degree of degenerative changes in the neurons than the others, and was especially interesting from the fact that the degenerated could always be found intermingled with approximately normal cells, affording an opportunity for an accurate comparison between the different elements. This brain was also remarkable for the beautiful staining of the nerve-elements of all the layers, which were exhibited in as perfect a manner as can ever be obtained in silver-preparations, and the sections were not disfigured by the presence of precipitate, even the external margins being free.

The lesions found in all the cerebra were closely allied to those found in the alcoholic brains that formed the basis of the first study. Cells of all layers were involved in the destructive process, the pyramidal of all varieties in the first order, then the deeper-lying elements, finally those of the extreme outer edge of the second layer and the elements of the molecular lamina.

A view of a section under low enlargement shows that the primary processes of many of the pyramidal cells no longer reach into the outer portions of the molecular lamina. Their finer dendritic branches have disappeared, while the thicker ones are filled with a multitude of coarser and finer knots, scattered with some regularity along the line of the stem. On the other hand, the thick intra-capsular portions of the dendrites have not become diseased in a similar manner, but apparently retain their integrity in so far that they are not altered in appearance by coarser changes, and seldom does the body of the cell present aught but its even, rounded contour. The basal processes are often likewise shortened, and show the knotty growths upon them like their ascending fellows.

Not every cell presents a similar degree of alteration, and according to the degree of involvement they may be divided into three classes: Cells in which the process is beginning; those in which it is moderately advanced; those in which the dendrons are very much degenerated. The normal cells in Brains 1 and 3 were comparatively infrequent; in No. 2, on the contrary, more that two-thirds of the stained cells were normal.

As the degenerative process is of similar character among all the classes of cells, we have taken the most prominent type, the pyramidal cells, as the criterion of the whole, as they are very much easier to study than the other, and have a definite size and anatomic characteristics, as well as stain constantly.

Class A, Cells Slightly Involved in the Alteration.

High up in the molecular layer we find upon the finest branches of the dendrons of the pyramidal cells, especially those of the long apical-process variety, a few tumefactions of either rounded or elongated form in the course of the stem. These tumefactions are deeply stained by the silver-salt, are smooth, and have few or no gemmules attached to their sides, or, when these are still present, there are perceptible differences in the tingeing with the silver-salt that indicate an alteration in their structure. Both nearer the cellular body and distally from the swelling, the dendrite appears to be perfectly normal, the staining is good, and the pin-like lateral buds are numerous. In these neurons the

coarser branches and the corpus of the cell are undisturbed by any alteration apparent to the micro-

Fig. 1.

Pyramidal cell from the mid-portion of the second cellular layer of the rabbit's brain, showing commencing tumefactions of the protoplasm of the finest apical dendrites, and denudation of the gemules at the points of swelling. At the uppermost forkings of the ascending dendron a normal enlargement of the protoplasm is seen, which is covered with gemules. Ax., axon.

scopic examination, and, indeed, the slight swellings on the finest twigs would occasion but slight comment were no other cells more deeply involved.

Class B, Cells Moderately Involved by the Degeneration.

This type is the most numerous of all. The tumefactions before present only on the finest dendritic branches now extend throughout the entire path of the stems of the apical and basal processes, reaching up or down to their intra-capsular portion, and many of the finest branches are no longer stained, and are apparently totally degenerated, having been partially or totally removed. The number of the swelling varies greatly in the different involved cells. Usually the dendrons have a large number of small thickenings along their course, and present a true moniliform appearance. Less commonly there are only a few of larger size, but the result to the nerve-process is the same. These large-sized swellings are peculiarly frequent at the forkings of the branches of the apical dendrons, where there is normally a thickening of the protoplasm. Rarely one meets with dendrons in which the smaller swellings are so numerous that they are coalesced, and only are noticeably different from the normal dendron by the irregularity in their contour and the loss of the lateral buds. In all the varieties there is an absolute loss of the gemmules on the dendritic processes, which eventually proceeds to a complete stripping of the dendron of all its fine rectangular pin-like processes. This denudation of the gemmule varies considerably on the different dendrons according to the number and advancement of the swellings. When the stem has only a few tumefactions the intervening spaces usually retain some of the buds, but when the swellings are numerous or very large they progressively disappear, until in a very large number of instances not only the finest branches are stripped of them, but the thicker portions are equally bare.

Following the swelling and loss of the lateral buds comes a contraction of the protoplasm of the dendritic twigs, especially that portion not involved in the swelling, though these also eventually atrophy. In the spaces between the swellings, as the process advances, the diameter of the branch grows less and less until it is reduced to a mere knotted thread. Then comes a time when there is a breaking up of the continuity of the twig. The finest branches fall off from the thicker stems, and are finally absorbed, the neuron now being reduced to the corpus of the cell, with the stumpy tumefied remains of the thicker dendrons attached to it.

I wish particularly to draw attention to the loss of the finest branches of the dendrites within the

Fig. 2.

A cell of different form from the same region of the cortex, showing an increased number of swellings and greater loss of gemmules.

limits of the molecular layer, a region of the utmost importance in the physiologic economy of the cortex. Here the branches of the dendrons, by means of their gemmules, come into contiguity with the

terminations of the nerve-fibers and end-apparatus of all descriptions belonging to the several classes of nerve-fibers, tending thitherward from the interior regions of the cortex—fibers from the cord and opposite hemisphere, fibers from the fusiform and other cells of the lowermost layers of cortical cells, collaterals from the pyramidal cells, also to some extent from the intermediary cells. Here all meet in close relation with the terminal branches of the pyramidal, and in the rabbit the bicornuate cells, and the nerve-impressions are carried through the medium of the bulbous tip of the gemmule and its stem to the protoplasm of the branch, and through this to the body of the cell.

It may be readily seen that, according to this arrangement of the fibers, no matter how small the swelling of the dendron and loss of the gemmules may be, there is an instant disruption of the close connections between dendron and nerve end-apparatus, and consequently imperfect carriage of nerve-impulses from neuron to neuron; and should the destruction proceed to any considerable extent, and involve a moderate number of the protoplasmic extensions of the nerve-cells, that a serious disturbance of the mental and motor functions of the cortex will result, ending eventually in partial or complete annulling of all the mental faculties of the animal.

None of the bodies of the cells of Class B shows any noticeable alteration in structural arrangement, the destructive process having apparently to advance to a greater degree than is found with the moderate degeneration of the dendrites.

Class C, Cells Extensively Involved in the Degeneration.

This class is almost entirely absent from the cortex of Brain No. 2, but in the other cerebra it constitutes a moderate proportion of the diseased cells. especially in Brain No. 3. The dendrons are now shortened to mere stumps; the finer branches have entirely disappeared; the coarser ones are irregular in outline and have large and small swellings upon them, and are much thinned, very often terminating in an enlargement at a short distance from the cell-body, having a thin, pointed projection extending out of it in the direction of the line of the former process. The gemmules have now entirely disappeared, not a single one being visible on the portions of the dendrites that remain. The cell-body presents under these conditions two entirely different appearances, even when the dendrites are disintegrated equally. In the first one the cell-body, where the processes have almost disappeared, retains its smooth and rounded form; seldom, indeed, is it roughened, and to all appearances the condition is one of health. In the other class the protoplasmic extensions have the same general aspect, but now the corpus is distinctly involved in the destructive metamorphosis. The edges of the cell are roughened and irregularly eroded; deep

excavations proceed from the periphery toward the central regions of the body; and, in exceptional and very advanced instances, nothing but a mass of detritus, blackened by the silver-salt, is seen occupying the site of the cell-body. In the last event nothing but the barest traces of the prolongations of the cell are to be found.

The nerve-fibers of the layers are quite freely stained in many of our sections, but even when the degeneration of the dendrons or of the cell-body is particularly well marked there is no lesion of this portion of the neuron. Cells that are greatly frayed and eroded in their bodies have perfect neuraxons,

Fig. 7. Fig. 8.

Fig. 7.—Micro-photograph of the finer portion of the ascending process of a normal long-stemmed pyramidal cell, showing the arrangement of the gemmules.

Fig. 8.—Ascending process of a pyramidal cell from a serum-brain from the same level as Fig. 7. The tumefactions and loss of the gemmules are very distinctly shown.

Fig. 9.

and these may be traced far downward into the white medullary layers. Cells that are apparently almost totally destroyed are too few in number to allow of any accurate knowledge of their axon. The collaterals of the axis-cylinders of the pyramidal cells may be followed to their bulbous free extremities; nor do fibers coming from more distant regions and passing upward, to terminate in the molecular lamina, show anything but a perfectly natural condition. There is no increase of varicosity, no breaks in the staining of the nerve-thread, no difference in the appearance of the terminal apparatus.

9*

Cortex of the Cerebellum.

The changes in the nerve-bodies resemble those in the cerebrum, but are less intense. The twigs of the Purkinje cells are often bared of their protoplasmic fur, have an occasional swelling, but are not highly degenerated. Normal Purkinje cells preponderate over abnormal ones. The free extremities of the dendrons show the alterations to a greater extent than the ones closer to the corpus of the cell, as if the swelling were just beginning. The neuraxons of these bodies are distinct and perfect. The *Korbzellen* stain infrequently, and nothing definite can be said of them. The Golgi cells are well shown, but alterations in them are slight.

Very numerous axons from the *Korbzellen*, Golgi and recurrent branches of the Purkinje cells are well stained in the molecular layer, but show nothing abnormal. Some beautiful specimens of the arborescent endings of the fibers intermingling and terminating among the branches of the Purkinje cells were found, but they also were perfectly normal, to all indications. The neurogliar structures, both in cerebrum and cerebellum, stained in numbers neither above nor below the control, and show no structural changes in their protoplasm deviating from the normal preparations. The degeneration of the nerve-cells is, therefore, probably a simple non-inflammatory process, unaccompanied by any proliferation of the supporting elements.

While the small number of the pathologic serum-brains does not allow us to speak with entire positiveness of the lesions of the cortical cells, yet from their constancy in all our preparations it is more than probable that we have found a new class of degenerative changes of the nerve-cell that will ultimately prove of the greatest importance in a long series of irritative abnormal conditions in the human subject, and will also open up a new field for the student of mental changes.

The absence of vascular lesions of importance precludes the possibility that alterations of nutrition from disease of the vessels are of the first importance in the production of the degeneration of the dendron. Much rather would we refer them to the direct action of the toxalbumin upon the cellular protoplasm, causing, in some unknown manner, at first swelling of the substance of the dendron, and later atrophy and destruction.

The Death of Dr. J. W. H. Walker.—At a meeting of members of the class of 1893 of Jefferson Medical College, on Thursday, August 22, 1895, resolutions were adopted, deploring the untimely death of their classmate, Dr. J. W. H. Walker, and expressing sympathy for his family in their bereavement.

Prof. Hoppe-Seyler, the distinguished physiologic chemist and Professor of Physiology and Pathology in the University of Strasburg, died suddenly in an apoplectic seizure on August 12th.

CLINICAL LESSONS.

Hysterical Contractures.

BY S. WEIR MITCHELL, M.D.,
OF PHILADELPHIA;
PHYSICIAN TO THE ORTHOPEDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES.

(Concluded from page 206.)

I DISMISSED last week a case of contracture in which the legs were in extension. I read you the notes as an interesting contrast to the flexor-spasms just described. I like also to speak of this case because it illustrates one very rational way of dealing with a partially developed hysteria, for really, despite a long history, it was undeveloped. A year or so more at home would have given us another bed-case.

Annie P., an unmarried white girl, seventeen years of age, was sent to me for treatment, and was admitted to the Infirmary, November 3, 1894. The family history was negative. She had four brothers and five sisters who were living and well. The patient was a small child at birth, but always enjoyed good health. She had the ordinary diseases of childhood, and a slight attack of typhoid fever, and attacks of influenza in 1890, 1891, and May, 1892. After partial recovery from the last attack she suddenly began to suffer from pain in the right heel and the arch of the foot, with a feeling as of a "large stone in the shoe." Hot water gave relief. The pain returned, and was now better and again worse. The heel and indeed the whole foot, and later the calf and the outer side of the thigh, became very sensitive to touch, and were also the seat of much spontaneous pain. Later, pain appeared in the left heel and spread similarly.

About one year after the first attack the girl was suddenly seized with acute and severe pain in the sacrum, which crawled slowly up the whole spine. Motion of the arms and legs, she said, made the pain worse. She now took to her bed (May, 1893). In one day, soon afterward, she became rigid, with the arms spread out laterally, the head retracted, and the legs extended. Pain was then severe in all the extremities, but not alone in the shortened muscles. It gradually grew less toward evening, but the rigidity continued. The patient was never unconscious. During the summer of 1893 she recovered sufficiently to walk a little, but she still had great back-pain and frequent relapses.

In October, 1893, after walking "too far," she was given a hot bath. When taken out she fainted, and had "heart-failure" and frequent trouble with her heart afterward. She was almost constantly on a bed or sofa from that time, and had occasional attacks of asthma during the year before coming under observation. Menstruation, regular and painless before the present trouble, was still fairly regular, but the flow was very dark and offensive, though quite free. Otherwise there were no signs of disease of the genito-urinary organs. The appetite was fair, considering the very long confinement. Digestion was good. The bowels were costive.

Examination showed a slightly built, anemic looking girl, weighing 83 pounds. She said that at twelve years of age she weighed 97 pounds. She was very much emaciated, especially in the legs. The growth of hair was unusual and excessive for her age and sex, all over the body as well as on the head. The skin was in good order, and the nails smooth and well formed. All touch anywhere on the legs and feet was painful, especially on the inner aspect. This sensitiveness varied from time to time. A slight touch was painful; pressure excessively so. The nerve-trunks seemed no more tender than the muscles. Two points were nowhere distinguished as one on the feet at less than an inch, and at a slightly less distance on the legs. The temperature-sense was normal. The abdomen was not sensitive, and there were no hysterogenic zones in the ovarian regions.

The girl was without pain in the arms. There was apparently a slight thickening about the spinous processes in the lower dorsal region, and the processes were excessively sensitive. The whole spine and the gutter on both sides for a distance of an inch-and-a-half or two inches was very tender, with areas of exquisite hypersensitiveness between the shoulders, at the waist, and over the whole sacrum. Firm pressure with the palm of the hand over the sacrum was less painful than touch. Use of the arms, she said, increased the spinal pain and tenderness. The knee-jerk was slightly increased, and easily reinforcible by motion and sensation. There was no clonus. Elsewhere the muscular and all other reflexes were normal. A presystolic murmur was heard at the base of the heart and along the left side of the sternum, and faintly in the axilla and at the apex. The pulse, which was soft and wanting in fulness and force, varied from 100 to 120. Respiration varied from 30 to 50.

It is rare to see as great sensitiveness to touch as Miss P. exhibited, and still more rare to find the muscular tissues sensitive. As to contracture, the condition found was rare and curious. The extensors and flexors all felt firm, but the result was a stiffening of both legs in extension. The feet were less drawn. The arms were not in a state of contracture. All efforts to flex and, after flexion, to extend the legs met with that continuous yielding resistance common in spastic states, and to which long ago I gave the name of "lead-pipe" symptom.

At my second visit I ordered the girl to walk, and, despite her disbelief in her power to obey, she was able with small help to get up and take a dozen steps, during which the heels did not touch the floor. Two years on bed or couch made this exertion difficult. But having once given her reason for hope, I put her back in bed, and for two weeks forbade exercise, while massage and tonics and good diet were employed. She gained rapidly in flesh. The corpuscular blood-count doubled after a week of massage;[1] all the functions began to re-

[1] See paper by John K. Mitchell on the "Influence of Massage on the Blood-count." American Journal of the Medical Sciences, 1894.

sume their orderly action. She was then allowed as a favor to rise and walk, and two weeks later was able to go home in excellent condition.

In the present case I insisted on this bed-ridden girl walking. I showed her that she could do so, and promised her that the pains in the back and leg would leave as she grew more and more able to exercise. Had I failed as to my predictions I should have doubly injured the case, but when one has had a long experience with hysteria it is easy to select the cases for abrupt exercise of authoritative influence. There were doubt and tears, but she walked, as ordered.

There is much to dwell upon in the cases I have brought before you. But now it is, above all, the prognosis and the treatment to which I desire to call attention. Charcot has said that very marked decrease of faradic contractility ought to make us suppose that the spinal cord has been invaded, and that the existence of a spinal organic lesion of more or less gravity will be placed almost beyond doubt, if, under the influence of deep sleep induced by chloroform, rigidity of the members only gives way slowly, or even persists to any marked extent, or if with this the faradic reactions are greatly lessened.

You will have seen that I do not altogether agree with this great student of disease, and that I approach these cases in a far more hopeful mood than I could do if I accepted the despair that his dictum would bring.

The treatment need hardly be set forth in detail. Above all, get your hysteric away from her audience. A hospital-ward is no place for her. But if you cannot deal with her elsewhere, treat the case as commonplace or trivial, and call no attention to it. For the rest, all the toning means are of use, and there are moral tonics not to be neglected, but for which a prosperous hour must be chosen.

It is well to say that the more you can improve the nutrition of joint, muscle, and nerve by mechanical and electric tonics, the better will be your chances of success when at last section of tendons becomes desirable.

I have put aside a final case of contracture in the male because of the doubts I long entertained as to its origin.

W. H. G., thirty-three years old, an unmarried railroad-clerk, was sent to me by Dr. W. S. Beebe, of Kirkwood, N. Y. Dr. J. E. Talley has made the following notes of his case: The man's father is living and well. His mother died of typhoid fever at fifty-seven years of age. He has one sister, in good health. There are no known family diseases. The patient himself had the ordinary diseases of childhood, excepting scarlet fever. He had pneumonia at nine years of age. He never drank to excess, nor has he ever abused the tobacco-habit. He certainly has had no syphilis.

The series of ailments that ended in what you see began with bronchitis in 1890. His physician said that at the time he was run down from overwork, and ordered him to take a vacation. He went away for two months and returned to his desk feeling much better. After working for a month, he was on November 6, 1890, "seized with chills," and had three in succession. After this he was confined to bed for fourteen weeks, suffering from what was described as "nervous prostration." His physician said that he had some lung-trouble, but that the major part of his illness was mere lack of power. It was not until five months later (April, 1891) that he was out of bed permanently, and was only able to walk with canes. He had then to use his eyes in walking, and was unsteady on closing them and in trying to stand. At this time, he tells us, the knee-jerk was present, and this is probable, as the patient is very intelligent and has studied his symptoms assiduously and closely.

During 1891 he got much better, and walked without a cane, except when going a long distance. He still continued to cough more or less during this time.

In March, 1892, he felt well enough to go down to El Paso, Texas, to take charge of an office. There he lost his cough, gained in weight, and was doing very well until August, 1893, when a "very dear" friend and fellow-worker died of hemoptysis. The shock of this loss, coupled with extra work, seemed to be too much for him, and again he began to fail.

From September 1, 1893, he had pains in his feet, which continued until December, 1893, when he took a mustard foot-bath for their relief. On the following morning he awoke to find his legs drawn up at the knees, just as they were when he came to me for treatment on March 15, 1894. The thighs were rigidly flexed on the abdomen at a little less than a right angle. There was also spastic adduction of both thighs. No other contracture existed at that time or since, except of the gastrocnemii. The contractions, however, continued to become more complete and more rigid. As to sensation at this time the man remembers nothing of value.

On admission to the Infirmary the contracted and symmetrically wasted state of the lower limbs described was very apparent. The right foot was flexed firmly against the buttock, a forcible pull on the foot being required to separate the heel from the buttock. The left foot and leg were in the same position, except that the heel could be separated from the buttock a distance of a foot-and-a-half by force. The hamstring tendons on both sides were very rigid, as were also the muscles of the thigh and leg on both sides. The man could move the toes of both feet fairly well, but flexion and extension at the ankles were limited. There was absolutely no available power above the ankles, every muscle being rigid.

The patient said that the wasting of the limbs was really not great, as he had always been very thin. The circumference at the middle of the right thigh was 35 cm., of the left 35½ cm., at the mid-

dle of the legs on either side 10 cm. The whole body was extremely emaciated. The hands showed disproportional wasting of the interossei muscles and of the thenar and hypothenar eminences. There was no clubbing of the fingers. The dynamometer registered 55 in either hand. The spinal column showed nothing abnormal, excepting scars of previous cauterization.

Sensation was normal until we examined the feet. In the left foot sensation as to touch, pain, and temperature was absent on the whole dorsum, the anterior third of the sole, and the heel. The mid-region recognized touch. On the right foot there was an absence of sensation on the first, fourth, and fifth toes; touch was felt in the third and fourth toes on both surfaces; also on the dorsum and on the sole generally, except at the heel. It was nowhere normal on either foot, but improved above the ankle until at mid-leg it seemed perfect.

These facts are interesting, because there is no account of early loss of feeling. It seems certain, however, that this anesthesia must have been an early symptom. The overwhelming pain appears to have detracted attention from the merely negative sign, loss of tactile sensation.

Pain had been felt in the legs before contraction came on, but was never severe, and was taken to be rheumatism. The pain that came after the contractions had lasted fifteen days was more severe and of a different character. It grew to be at last the absorbing feature of the case.

There have been no bedsores or evidences of grave trophic disorder. Co-ordination was good in the arms and fingers. Station and gait, of course, were not obtainable, the man being bedridden and very nervous.

The knee-jerk was not obtainable on account of the spasticity of the muscles, nor could we get ankle-clonus or muscle-jerks in the legs. The epigastric, abdominal, and cremasteric reflexes appeared to be normal, as was the elbow-jerk. The man has never had incontinence of urine, but has had to be catheterized some five times since 1893. He has had no priapism; and, in fact, very seldom has an erection. He has also had perfect control over the rectum.

Dr. Archibald G. Thomson reported upon the eyes: "The pupils are equal and dilated. They react in accommodation, but not to light. The media are clear. The discs are a trifle grayish, the arteries small. The fundus is pale. The muscular balance is good."

There was no reversal or contraction of the color-fields.

With the man on his back, the chest-expansion was 1¼ inches. The percussion-note was higher-pitched above the right than above the left clavicle, and a full inspiration heightened the pitch on the right side and but very little on the left. The whole right side moved less than the left. Respiration was a trifle harsh at the left apex, and expiration was here prolonged and more marked than inspiration, but of about the same pitch as elsewhere. There was very little change in vocal fremitus and resonance on the left side, but on the right chest anteriorly the voice was conveyed much more clearly than elsewhere. On full inspiration there were moist rhonchi at both apices, more marked on the right. Posteriorly the eleventh rib on the left showed a prominence, as if it had been broken.

On having the patient sit up it was observed that the left nipple was slightly higher than the right. The right chest moved more (½ inch) than the left during respiration. A musical murmur, systolic in time, was heard at the end of expiration over the base and at the apex of the heart. The apex-beat was found to be in the fourth interspace, with the greatest impulse at the sterno-costal junction.

Staining the sputum for tubercle-bacilli was negative; urinalysis also was negative.

It was evident that the lung-condition had nothing to do with the paralysis. There was much difference of opinion as to the cause of these very interesting contractures. The absence of a previous hysterical history led some of our staff to regard the case as one of spinal hemorrhage.

As to treatment I had no indecision. The great flexion of the thigh on the pelvis, as in Miss C.'s case, kept the sciatic nerve stretched at the notch. There was but one remedy. As to what more we should win besides relief from pain I could not anticipate.

At my desire, on March 29, 1894, Dr. Keen operated on the right leg, dividing the thigh-muscles at their attachments to the pelvis; also the inner and outer hamstring tendons. He could not bring the leg to a straight position even then on account of the rigidity of the parts, and for fear of tearing the contracted femoral vessels. The limb was dressed, a double-inclined plane and extension-weights applied, these to be gradually increased. The extension-apparatus slowly accomplished its purpose, but was somewhat hampered by the development of a small bedsore over the sacrum as a result of the necessity of keeping the man constantly on his back. This soon healed, and the limb was then more actively extended each day by increasing the weights.

As this extension at once eased and soon put an end to pain in the leg on which Dr. Keen had operated, it was thought well to treat the other limb in like fashion. This was done June 19, 1894.

On December 7, 1894, both Achilles' tendons were severed. The patient has now no pain, and has gained from day to day and month to month in the straightening of the limbs, in moral courage, and in increasing freedom from nervousness.

Except for an attack of diphtheria, which necessitated removing the man to the Municipal Hospital in December, 1894, until January 22, 1895, he has been making constant improvement. His present state (February 4, 1895) is as follows:

A faint systolic murmur is heard over the apex of the heart and at the base. No circulatory disturb-

ance exists. The lungs have cleared up. There is no cough or expectoration. The hemoglobin-value of the blood is 95 per cent., and the man looks ruddy. There is an absence of the neurotic facies. The muscles are less wasted, but firm, and respond well to the faradic current everywhere, even in the legs. There are no tender spots on the body and no evidence of neuritis. The man controls his bowels and urine normally. There is no priapism or other abnormality of the genital organs. The weight to-day is 101¼ pounds, being a gain of only 6¼ pounds since admission to the wards.

There is still general emaciation, but the thighs and legs are somewhat more wasted than other parts of the body. There are to be seen the scars of the operations on the thighs and legs. There are no excoriations, no clubbing, or other evidences of trophic disturbance other than those caused by lack of use of the muscles.

The right thigh is in a straight line with the abdomen as the patient lies on his back. The leg can be extended to an angle of 170° with the thigh. The right ankle is perhaps a little extended, the toes being slightly flexed.

The left thigh is also in a straight line with the abdomen, as is the left leg with the thigh as the man lies passively on the bed. The ankle, foot, and toes are in good position.

Both thighs can be freely flexed, adducted, and circumducted, and there is the same voluntary control over the knees, legs, and ankles. The toes are less freely movable. The man walked five feet with the assistance of the nurse and a chair to-day. The grasp is good and equal, and no other motor palsy exists.

The patient has taken tonics, cod-liver oil, etc., and since September 17, 1894, he has had massage and movements with faradism daily to the affected limbs.

Early in April Dr. William J. Taylor divided the muscles on the inner side of both feet. This was needed because of the swelling and pain in the feet when the man was long afoot, and which seemed due to the cramped form of these parts.

On May 11, 1895, the man was walking a little on crutches—and improving. After exercise the feet were still more or less painful. He has steadily grown better up to this date (June, 1895).

The case, as you have heard it, does not enable us to be sure as to the immediate cause of the trouble. G. has been asthenic—neurasthenic, if you please; he recovers, goes South, and, as a railway-clerk, is overtaxed and much worried. For ten days he has aches in the legs, and awakens at last with his legs drawn up.

Are these hysterical contractures? At first they could be relaxed under ether. Must we accept Charcot's dictum that this is a certain sign of their hysterical origin? There was probably some early loss of sensation, but if, as has been suspected, these spasms were due to a hemorrhage within or on the cord, we might well have had this symptom. I confess that there was too little disturbance to allow me to entertain the latter diagnostic theory. Here is a man who sleeps well and awakens with great and increasing contractions, and probably with more or less anesthesia. In time the reflexes fail or lessen; the electric reactions are quantitatively diminished, and the mechanical reactions lost. All this might come from a neurotic, functional spasm, and it all reads like the progressive story of an hysterical disorder. It differs in no wise from the cases of Miss C. and Miss H., except that there are no other hysterical signals flying, such as their more complete hysterias too fully show. Also in this (G.) case the reflexes have come back, the electric reactions are all better, and here and there we can call out movement by a blow with the hammer. At present G.'s legs are straight, or nearly so, and the muscles are all improving. Where and when these gains will end I do not know; but certainly so far, in the light of treatment, the case does not read like one of organic disease of the cord, nor like any form of neuritis.

My conclusion is that in this case we have hysterical contractions in the adult male, a rare phenomenon, in this country, at least, where we have the nervous temperament, but are not neurotic to the extent seen in the Latin races.

Fortunately these general contractures are rare. But, whether general or local, if they have proved during four or five months amenable to no medical means, then I counsel the use of the knife and the section of tendons. It is true that Charcot and others have described cases in which, after years, contractions ceased abruptly and the limb was as before. The statement should have had a long appendix of exceptions. In cases of moderate contracture, not drawing the part to an extremely acute angle, sudden recovery may leave the joint undamaged. But in grave cases this never can be the case with joints like the knee, which is always the most difficult articulation to deal with. A long, violent contraction of the flexors partly luxates the tibia backward, and results in joint-changes which, after years of contraction, are incapable of cure.

In these knee-cases, perhaps in all articulations long out of place, there is probably soon or late more or less of that kind of inflammation which is also seen in joints too long on a splint. If this be so, a part of the failures to respond to electricity may be due to the muscular wasting so commonly observed in connection with damaged joints.

But, whatever the cause, I have seen hysterical contractions in which, after section of tendons, the joints were too much altered to admit of useful restoration. The leg, bent at an angle of 45°, is brought, by section and the screw, to a much larger angle, but cannot be made straight enough for use. There is motion within limits, but with weak muscles and bent legs the effort needed for walking becomes

excessive. Under these circumstances crutches are essential, and there may arise a question as to the propriety of making the leg straight by an operation that will leave it rigid. Above all, I desire to impress upon you finally that a contracted limb is not a limb to confide to the rare relief brought or not brought by time.

I have desired to call attention in this paper to certain hitherto unnoticed clinical facts:

1. Two forms of hysterical contracture exist. One concerns single parts and limited groups of muscles. In this the contracture may last for years without the addition of organic changes in muscles, joints, or interstitial tissues. In this also sudden cessation of contracture is possible.

2. A form of contracture exists which attacks in succession one limb after another, until soon or late all or nearly all the voluntary muscles, as well as those of the trunk, may become involved. The cases of this group do not, in my experience, ever get well abruptly. In them the muscles, joints, and areolar tissues undergo serious organic changes.

In the first or limited form the muscles and the muscular reflexes remain unaltered, or are but little changed, and mechanical and electric responses continue to be normal or nearly so. In the second or generalized form, the reflexes are lost or interfered with late in the disorder, and the electric responses are quantitatively lessened, and may, in time, be almost altogether lost. It is only in this form, after years of life in bed, that we may expect to see changes in the cord. Whether these are merely independent accidents, or are the rare secondary products of the hysterical condition or of the organic changes this occasions in the peripheral nerves and muscles, we do not yet know.

ERUPTIONS SIMULATING THAT OF SCARLATINA.

By J. P. C. GRIFFITH, M.D.,
OF PHILADELPHIA;
CLINICAL PROFESSOR OF DISEASES OF CHILDREN IN THE UNIVERSITY OF PENNSYLVANIA; PROFESSOR OF CLINICAL MEDICINE IN THE PHILADELPHIA POLYCLINIC, ETC.

THAT the rash of scarlet fever can be closely simulated by various other eruptions is a fact, unfortunately, only too well known. The difficulty in diagnosis depending upon this similarity is often so great that a recapitulation of some of the conditions that may give rise to the confusion may not be amiss, although no attempt can be made to enumerate them all. Certain cases that have occurred in my own practice have been so puzzling at the time that some of them may be used by way of illustration of the points to be brought out.

As a matter of course, no disease can be studied from a single point of view or in the light of one symptom merely. Were the rash of scarlet fever all that physicians had to guide them, they would be far oftener at sea than they now are. On the other hand, could they always see the end from the beginning; could later symptoms, in the nature of things, appear with the first development of the rash, errors in diagnosis would be much less frequent.

To the matter of diagnosis in general, and to the ordinary symptoms of the disease, but little attention need be paid in this connection. The later course of the case usually makes the diagnosis plain. It is only the comparative study of the cutaneous eruptions that interests us at present.

The eruptions that most often resemble that of scarlatina are various forms of erythema. One of the most puzzling, although comparatively less frequent conditions, rendering the diagnosis of scarlatina difficult, is the occurrence of an erythematous rash attending tonsillitis. A cursory examination of medical literature has not shown me much written upon the subject, yet the condition is one that undoubtedly occurs. Its recognition is all the more difficult on account of the fact that the combination of sore-throat with eruption is exactly what we would expect to find in scarlatina. A few years ago I saw the following very characteristic instance of the condition:

An adult woman was admitted to the Hospital of the University of Pennsylvania, suffering from tonsillitis. A few hours later it was noticed that she was covered with a not very well developed rash, having all the characters of that of scarlatina. By the next day the rash had disappeared, and no desquamation followed, making the diagnosis of erythema reasonably certain.

It is, indeed, only to be expected that cases like this should occur frequently, when we remember that both erythema and tonsillitis are often local manifestations of rheumatism. I have known of cases in which there was no question of the rheumatic nature of the scarlatiniform rash, in which tonsillitis and an erythema exactly resembling the eruption of scarlet fever were associated with articular and cardiac manfestations of rheumatism. Such a case, too, was recently reported by Boyd,[1] in which tonsillitis was followed by a decidedly persistent erythema, with pain in the fingers and wrists, and in which, although scarlatina was at first strongly suspected, the later course of the case and the articular involvement removed all doubt. Sometimes, it must be remembered, we find cases that we suspect of being merely tonsillitis with erythema, but which turn out to be scarlatina. Instances of this nature show the importance of insti-

[1] Medical Record, February 2, 1895, p. 143.

tuting proper treatment and quarantine in all doubtful cases.

The condition known as surgical scarlatina may be considered in this connection. It is to some extent a very puzzling one, and one about which writers are not agreed. Some make the statement that surgical scarlet fever is simply scarlet fever occurring in a surgical case. Others take the ground that the disease is a manifestation of septicemia. It seems certain that some of the cases, at least, are not examples of scarlatina, although greatly resembling it at first. The distinction is most important, as the question of the danger to others must be considered. The following case illustrates the occurrence of septic erythema resembling the rash of scarlet fever:

M. S., aged eleven years, a patient at the Children's Hospital, suffered from caries of the right fibula. On November 15, 1894, a large sequestrum was removed by Dr. John Ashhurst, Jr. The temperature remained at about 100.4° until November 20. During the night from the 19th to the 20th there was found a rash covering the whole body, which was described in the clinical notes as "measly," and which extended from the roots of the hair to the soles of the feet. The temperature fell to normal when the rash developed. On November 21, at 8 A.M., the rash was still macular, but no longer looked like that of measles. By 11 A.M., at the time I first saw the child, the eruption looked precisely like that of a well-developed scarlatina. The throat was slightly red, the general condition excellent. There was still no fever, and the pulse was 92. On November 22 the rash was fading. On November 23 it had almost gone; it left an appearance like slightly injected "gooseflesh." On November 24 the condition was much the same. On November 27 all signs of the rash had gone. No peeling followed.

No isolation whatever was practised in this case, as the diagnosis was made early. Had the disease actually been scarlatina it is scarcely possible that other children would not have contracted it.

The disease known as puerperal scarlet fever is of the same nature as the surgical variety, viz.: usually erythematous and of a septic origin. Of course, true scarlatina may occur in the puerperium.

Another, and a very curious instance of an erythema that had considerable resemblance to the eruption of scarlatina is the following. The origin of the attack in this case I was never able to discover:

Mamie McF., aged seven, presented herself on June 30, 1890. She had been perfectly well the day before; had slept well, and had had no vomiting or fever. She woke in the morning covered with a rash, which the mother said looked then as it did when examined by me at about 11 A.M. At this hour the face was slightly swollen and puffy, and an indistinct reddish color was visible about the nose and chin. The eyes were not suffused. Over the front and back of the chest, and on the arms and thighs, there was a perfectly smooth, rose-red color, resembling in appearance in the denser portions more the eruption of erysipelas than that of scarlatina, inasmuch as there was an entire absence of the punctate mottling that characterizes the latter affection. In the less dense portions of the color the likeness to scarlatina was more pronounced. On the legs proper, and on the wrists, were some few papulo-macules the size of peas, and larger in area. The temperature was 98.6°. There was no redness or swelling in the throat, and no enlargement of the superficial cervical or other glands in the neck. The tongue was clean, and without enlarged papillæ. On June 21 the eruption was entirely gone.

This case might easily have deceived the unwary. Close examination would, however, have made one suspect rather the existence of *rubella scarlatiniforme*, to which reference will be made later, especially in view of the presence of the macules on the extremities. The sudden and complete disappearance of so extensive an eruption placed it beyond doubt in the class of the erythemata.

A scarlatiniform rash occurring after the administration of enemata has been described by Suckling and others. It has never been my fortune to meet with this. Very often the diagnosis between scarlatina and some of the rashes resembling it can be made only by the later course of the attack. If the peculiar peeling takes place we have good reason to suspect that we have had to do with scarlatina. This applies to the diagnosis between this disease and rubella and most of the instances of erythema, but it is a rule by no means without exception. That is to say, the absence of peeling would render the existence of scarlatina rather improbable, but its presence is not certain proof that scarlatina has existed. The following case is an illustration in point. It is probably to be considered one of septic erythema.

Helen P., aged ten years, had undergone an operation upon the septum nasi on November 28, 1894. On November 31st there was no fever, but pain in the nose. On December 1st, in the evening, a rash was found on the chest. There had been no premonitory symptoms, and the child had been well all day and apparently free from fever. The rash was bright red and extended over the front of the chest as far as the lower ribs and high into the armpits, but did not reach the back. The skin was perfectly smooth. The itching was quite annoying. On December 2d the eruption was paler in the morning, but bright again in the evening. The child had vomited, but this was after taking castor-oil. The general condition was good. On December 3d the rash was paler and peeling had commenced. This was identical with that seen in scarlatina, and was most marked in the armpits.

Of course the limited area of the eruption was almost sufficient to negative the diagnosis of scar-

latina, even without taking into consideration the absence of other symptoms. Yet we cannot make the limitation of the eruption to certain parts of the body a test for the absence of scarlet fever. As a matter of fact, the extent of the eruption is no guide in diagnosis. In malignant cases, as is well known, little if any rash may appear at any time. In very mild cases, too, the rash may be very limited in extent, as the following case illustrates:

Willie C., eighteen months old, while apparently still in perfect health and without fever, yet exhibited a slight erythematous rash upon the inner side of each thigh. I supposed it to be simply a slight erythematous eruption from an unknown cause, and gave this as my opinion. A short time later the characteristic peeling of scarlatina took place. Scarlet fever occurred, too, in another member of the family.

Cases far more puzzling than that of Helen P., already related, have been reported. For instance, we may recall the interesting ones published by Blanc,[1] in which recurrences of a widespread eruption, followed by desquamation, had several times caused physicians to make the diagnosis of scarlet fever in two patients. Similar cases have been observed by others both in this country and in Europe, and the disease has been given different names, such as *erythema exfoliativum recurrens*, *erythema scarlatiniforme*, etc.

There are other conditions that might cause difficulty in diagnosis if we depended upon the rash alone, and which, indeed, may sometimes give us trouble in spite of careful study. Various drugs are capable of producing an erythema that may look much like that of scarlet fever, although it oftenest takes the form of a maculo-papular rash simulating that of measles. Thus, for instance, quinin is capable of producing a scarlatiniform eruption. Antipyrin may do the same, although the antipyrin-rash is generally rubeolous in appearance. Copaiba may also bring out an erythematous rash. The use of the diphtheria-antitoxin has brought out the fact that this, too, or at least the blood-serum containing it, is capable of producing an eruption resembling that of scarlet fever. Belladonna may produce an eruption that may be very confusing. In the case of a little boy of ten years, suffering from scarlet fever, the homeopathic attendant had given so much belladonna that it was impossible at first to determine how much of the redness of the skin and dryness of the mouth was due to the disease and how much was caused by the drug.

A scarlatiniform eruption may occur in the course of different diseases. Rarely it is seen attending gonorrhea, independently of the use of copaiba, and it is then probably septic in origin. It may also occur with typhoid fever, usually early in the disease, and may exactly resemble the rash of scarlet fever.[1] As is well known, a scarlatiniform rash appears in many cases among the prodromal symptoms of smallpox. This may be widespread, although it is usually limited to certain regions of the body. In varicella, too, an erythema may be among the prodromes in exceptional cases. There have been a good many cases reported of the coexistence of varicella and scarlatina in one person. This does occur, but in many instances it seems very possible that the apparent combination has been due to the development of an erythema during the existence of varicella. Thus, in a case that I saw a few years ago, a child, while exhibiting the ordinary eruption of varicella, developed a rash that had all the appearances of the genuine eruption of scarlatina. I supposed that here was an instance of the coexistence of the two affections. However, the rapid fading of the color, the absence of any symptoms of scarlet fever, the failure of desquamation to appear, and the fact that no other children in the house contracted the disease, rendered it probable that the eruption was erythematous merely.

Diphtheria may sometimes, although not commonly, exhibit an erythematous eruption that is capable of obscuring the diagnosis. The fact that in malignant cases of scarlet fever the rash may be entirely or nearly absent, while the throat-symptoms are very pronounced, adds to the difficulty. Of course, the frequency with which diphtheria occurs in combination with scarlet fever is still another complicating factor. The case of Florence F., detailed later, illustrates the difficulty sometimes attending the recognition of either disease.

It would seem almost impossible that an affection with such a characteristic rash as measles could ever be confounded with scarlet fever, and such, indeed, is the case, if we are guided by the complex of symptoms of the two diseases. As far as the rash itself goes, however, it sometimes happens that the eruption of scarlet fever in malignant cases is a good deal like that of measles. In these cases a very imperfectly developed rash may be decidedly macular, although, it is true, it is nearly always in some parts sufficiently characteristic, with the presence of other symptoms, to render the diagnosis plain. It is rather scarlatina resembling measles than the reverse. The extracts from the history of the following case illustrate the appearance that the rash of scarlatina may sometimes assume:

Florence F., aged two-and-one-half years, was on March 5, 1895, taken sick with sore-throat and a scarlatina-like rash over the trunk. On the 6th the rash was poorly developed, while the temperature

[1] International Clinics, October, 1891.

[1] See article by Ohman-Dumesnil: Journal of the American Medical Association, August 2, 1890, p. 164.

was high. On the 7th a little white deposit was visible on the tonsils. The rash was now only slightly out. On the 8th large white patches could be seen in the throat; the urine contained albumin; the rash was more distinct. On the 9th the rash was more pronounced than the day before, and there was a diffuse, bright redness over the buttocks, but about the knees there were bright-red patches distinctly infiltrated with serum, and thus harder and slightly more elevated than the surrounding skin. On the right leg the rash was decidedly papular and looked not at all like that of scarlatina, but rather like that of measles. On the 11th the membrane was nearly gone from the uvula; the hands were swollen and red; the papular eruption was present about the wrists and knees, and several ruptured, flattened vesicles, like those of varicella, had appeared on the hands. On the 13th the throat was much better. There was, however, a good deal of discharge from the nose. The child was still heavy and stupid. On the 17th the throat was nearly clear; there was still much discharge from it and from the nose; peeling had begun two or three days before. On the 19th the temperature was still high, and membrane reappeared in the throat. On the 21st the general condition was evidently worse; the child was delirious; there was extensive sloughing on the right side of the throat inside and to less extent on the left. Cutaneous emphysema was present down to the upper part of the chest. The case need not be further followed. Klebs-Loeffler bacilli were found in the throat. The respiration became a little croupy and later distinctly stenotic. Membrane was discharged from the nose. The child died on the 26th.

The rash in this case was not at all characteristic of scarlatina. Although resembling much more that of measles, this disease could practically be excluded by the nature of the other symptoms. The more important question was whether we had here to do with diphtheria at the outset in combination with an erythematous rash; but the course of the disease, the temporary improvement, followed by a return of the throat-symptoms and the occurrence of peeling, make it practically certain that the case was one of malignant scarlatina, followed by diphtheria.

Finally, and perhaps most important, as it is most puzzling, is the fact that the rash of rubella very frequently simulates most closely that of scarlet fever—so closely, indeed, that in mild cases of the latter disease the diagnosis may be impossible until, perhaps, the characteristic peeling later clears up the uncertainty. So common is this similarity that in the article[1] previously referred to this form of the affection is designated *rubella scarlatiniforme*. The rash in these cases becomes universally confluent, is not at all elevated, and may exactly resemble that of scarlatina, except that one can usually find at the ankles or wrists a papular or macular marking at the edge of, or even in, the general diffuse redness. On this appearance the probable differentiation can often be based. So, too, rubella is likely to show at the beginning the macular rash, even though a diffuse redness appears in a day or two. Yet these diagnostic points, although of service, are very likely to play one false when most needed.

Cases of scarlatina occur in which the macular appearance of the rash on the extremities is quite evident; while, on the other hand, the eruption of rubella, unless studied throughout its whole course, may fail to exhibit any character that can be called distinguishing. The following two cases illustrate the difficulty that attends the matter. I frankly confess that in the first I made a diagnosis of rubella, and was afterward obliged to change it to scarlatina, while in the second the early diagnosis of scarlatina had to be substituted by that of rubella. In retrospect the diagnosis seems plain enough, but at the time it was most perplexing. The histories are given only in brief and with special reference to the appearance of the eruption.

Mattie C., aged four-and-a-half years, was on May 23, 1886, irritable. On the 24th she was feverish and drooping, and sick at stomach frequently. On the 25th a bright-red, diffuse rash covered the trunk. The thighs, legs and arms showed a mottled rash exactly like that of typical rubella. The eyes were slightly red; the throat somewhat sore. The existence of the mottling rendered the diagnosis of rubella justifiable, especially as the child seemed little ill. On the 26th the temperature was 100°; the throat was red; the tonsils were inflamed, and showed some white points. The tongue was bright red, except at a small central spot. The glands behind the sterno-cleido-mastoid were slightly enlarged; those under the jaw not so. The rash seemed evenly red everywhere. The case now looked more like one of scarlatina, although I did not believe it to be this on account of the previous mottled eruption. On the 27th the tonsills were still red; the rash was fading; it appeared elevated on the finger-tips, and somewhat on the legs. The child was feverish, and had talked in its sleep on the preceding night. The palms were deep red in color. A little earache was present, and also considerable pain in the abdomen. On June 1st the child was feeling in a manner entirely characteristic of scarlatina.

John P., aged twelve, came home from school on February 26, 1886, cold and feeling badly, and with an eruption developing. Later he had sore-throat, with some redness of the eyes, but no coryza. The rash was in the form of pea sized and smaller macules, and the disease was supposed to be rubella. On the 27th the rash covered most of the body, and was confluent in many places. On the 28th the rash was well developed, and so widely spread and so punctate and characteristic of scarlet fever that the diagnosis of this disease was substituted for the earlier one. The temperature and pulse remained only slightly above the normal throughout the attack. There was no characteristic peeling, and

[1] Medical Record, February 2, 1895.

these symptoms, combined with the earlier appearance of the eruption, make it clear that the first diagnosis was the correct one.

Numerous cases like the last could be cited, but they would simply be repetitions. In the majority I have been able, I think, to make a correct diagnosis, although not upon the appearance of the rash alone.

To sum up, then, we find that the eruption of scarlet fever is not only liable to vary decidedly in different cases, especially of the malignant or very light forms, but that other eruptions may resemble the typical rash very closely; that the erythemata are likely to be very evanescent, and that this peculiarity aids in recognizing them, but that they by no means need to be of this nature; that peeling in a characteristic manner occurs in most cases of scarlet fever, but this may occasionally occur, although fortunately rarely, in other conditions, and, sometimes, in scarlet fever it is scarcely perceptible; that it is even possible for the eruption of scarlet fever to suggest the presence of measles, and that the eruption of rubella can in very numerous cases, with difficulty, if at all, be distinguished from that of the more serious affection.

So much for the difficulties of diagnosis as far as the eruption itself is concerned. With regard to the means of determining that we have actually to do with scarlet fever, and nothing else, the subject is far too large to be entered upon in this connection. It need only be said that it is important, above all things, to endeavor to make the diagnosis from the *complex* of symptoms rather than from the nature of any *one*, whether eruption, fever, tongue, pulse, or what not. In this way the careful physician will usually arrive at a correct conclusion, though not always.

URETHRAL DIVERTICULA.

BY WM. S. BAGOT, M.D.,
OF DENVER, COL.;
PROFESSOR OF GYNECOLOGY, UNIVERSITY OF DENVER, COLORADO; GYNECOLOGIST TO ST. LUKE'S AND ST. JOSEPH'S HOSPITALS, DENVER; FORMERLY SENIOR ASSISTANT PHYSICIAN TO THE ROTUNDA LYING-IN HOSPITAL, DUBLIN, IRELAND.

URETHRAL diverticula or pseudo-urethroceles, though sometimes classed together with true urethroceles or dilatations of the middle third of the urethra, constitute a distinct affection, differing from the latter both in etiology and physical signs. The urethral diverticulum consists of a cavity or pouch situated in the urethro-vaginal septum, usually about the middle third and communicating by a narrow opening with the urethra, which is not dilated, but is of normal caliber. In one of the cases reported by Routh the cyst communicated with the urethra by two openings. These diverticula vary greatly in size, some being only the size of a pea, others attaining that of a hen's egg or even larger. In a case operated on by Lawson Tait the size of the sac "was probably as great as that of the bladder." The cyst in this case "ran backward as far as the cervix uteri, and seemed to double up on each side of this structure into small pockets."[1]

The contents of the diverticulum consist usually of pus and urine. In one of Priestly's cases sebaceous matter was found in the sac. Piaseski[2] reports a case, operated on by Serfioti, in which a pipe-shaped calculus, the size of three small hazelnuts joined together, had formed in the diverticulum. It consisted entirely of phosphates. Various theories have been put forward as to the etiology of these diverticula. Santesson ascribes their origin to trauma, inflicted during labor or catheterization, or to rupture of a vaginal cyst into the urethra. Lawson Tait, from an analysis of five cases that occurred in his practice, believes that they are congenital. Winckel records two cases, which he thinks were due to inflammation of the urethral lacunæ. In one of these the walls of the cyst consisted of muscular tissue and their inner surface was lined with pavement epithelium. Routh, in reporting three cases, two from his own practice and one that had been operated on by Percy Boulton, says their "etiology seems to be: 1. Closure of the ducts of pre-existing urethral glands, retention-cysts resulting. Suppuration and ulceration into the urethra by a small, often valvular, hole follows, and the inflammation is kept up by urine trickling into the sac at each micturition. 2. Blood-cysts which have passed through similar changes. 3. The formation of pseudo-cysts by injury to the urethral floor during labor or menstruation."

Boulton considered the origin of the diverticulum in his case to have been suppuration and rupture of a blood-cyst, the result of injury received during labor. The wall of the sac was fibrous, and firmly attached to the surrounding structures. "It was not a true cyst. It contained dark-red, fleshy trabeculæ, suggesting organized blood-clot, and had no epithelial lining." In one of Routh's cases the cyst-wall consisted mainly of connective tissue. Its inner surface was the seat of an inflammatory process; but no epithelium could be seen. The arrest of a vesical calculus in the urethra has been also considered as a cause (Piaseski).

The symptoms are usually frequent and painful micturition accompanied by the sensation of a firm, tender tumor in the vagina, which causes dyspareunia. A quantity of pus, usually ammoniacal and varying in amount according to the size of the sac, is passed from the urethra and may cause consider-

[1] Tait's Diseases of Women, 1889, vol. i, pp. 84, 85.
[2] Nouv. Arch. d'Obstét. et de Gynécol., 1892, p. 236.

able local irritation. Urethritis and cystitis are frequent complications.

Diagnosis. On examination a firm, tender swelling is found situated in the urethro-vaginal septum, usually about its middle third; but when the cyst is of large size its upper limits may reach the cervix or even further, and, as in Tait's case, pass up into the lateral fornices. On applying pressure to the tumor a quantity of thin ammoniacal pus is discharged from the urethra. In Santesson's case, however, compression of the tumor caused its contents to be evacuated backward into the bladder. By examination with the electric urethroscope the opening in the floor of the urethra can be detected. Should any difficulty be experienced in doing so, the pus will be seen welling up from the aperture on applying pressure to the tumor while the urethroscope is being slowly withdrawn. That the tumor is not a simple dilatation of the middle third of the urethra is shown by the fact that a large-sized sound, introduced into the urethra, does not enter the sac during its passage into the bladder; but by carefully searching along the posterior wall of the urethra with a probe the opening can usually be discovered and the probe passed into the cyst. Unlike a true urethrocele the pseudo-urethrocele can be palpated as a definitely outlined cyst after its contents have been expressed.

Treatment consists in dissecting out the cyst and closing the cut surfaces with silk or catgut sutures. Passage of the catheter after the operation is unnecessary unless retention of urine supervenes. After dissecting out the diverticulum, should the parts not appear sufficiently healthy to allow of immediate reunion, which will be of rare occurrence, a soft catheter is introduced into the urethra and allowed to remain for from two to four days. The wound in the septum is dusted over with iodoform and covered with iodoform-gauze. The cut surfaces are then allowed to granulate up, or secondary suture may be performed.

MEDICAL PROGRESS.

Gonorrhea of the Uterus.—At the meeting of the German Gynecological Society recently held in Vienna, Wertheim (*Centralblatt für Gynäkologie*, 1895, No. 26, p. 699) maintained that next to the urethra the uterus is the most common seat of gonorrheal infection. In most cases the infection is direct and in many restricted to the uterus. The symptoms are always of acute onset. The distinction between an acute and a chronic stage is legitimate, both clinically and bacteriologically, although a sharp line of separation cannot be drawn. The infection gives rise to inflammation of the uterine mucous membrane, at first manifested by purulent catarrh and leading up to an interstitial endometritis. In a not inconsiderable number of cases of chronic course there results glandular increase—*i. e.*, a glandular endometritis. In addition to the changes in the mucous membrane there occur in many cases inflammatory alterations of the muscular layer, characterized upon the one hand by inflammatory infiltration of the muscular connective tissue, and on the other hand by hyperplasia of the walls of the vessels, leading ultimately to hyperplasia of the connective tissue at the expense of the muscular elements. The swelling and painfulness of the uterus observed in many cases are to be considered evidences of the metritis. The inflammatory changes are progressively less intense as the external os is approached. In some cases gonococci are demonstrable in the inflamed mucosa in greater or smaller number. In many cases, however, this demonstration fails both with the microscope and by culture. The deeper the layers the more difficult is the demonstration of gonococci. It is probable that gonococci are present in the inflammatory infiltrate of the muscular tissue, but the demonstration is as yet wanting. These changes are to be viewed as due to the gonorrhea, first, because the gonococci have been demonstrated in the mucous membrane; second, because in none of the uteri examined have any other bacteria been found; third, because these changes were also marked in all cases (5) in nullipara. Mixed infection or secondary infection appears thus to be as rare under these conditions as in gonorrhea of the uterine adnexa. The internal os uteri seems not to act as a barrier to the ascent of the gonorrheal process. The exacerbations in gonorrhea of the uterus are frequently dependent upon alterations in the nutritive medium as influenced by various unfavorable conditions (such as menstruation and coitus). In many cases, however, they are dependent upon renewed infection. The puerperium is an exceptionally unfavorable state, as during this period an extension of the gonococci to uninvolved parts very likely takes place frequently.

A Case of Akromegaly, with Temporal Hemianopia and Glycosuria.—At a recent meeting of the Société de Biologie, Marinesco (*Le Mercredi Médical*, 1895, No. 26, p. 305) presented a case of akromegaly in a woman, thirty years old, with unusual manifestations. At the age of twenty-two years the patient had had epileptic attacks, occurring three or four times weekly, without aura, and with progressively diminishing frequency. Five years before coming under observation she was seized with vertigo and fell down two flights of stairs. Six months later it was noticed that the feet were increasing in size, and soon a similar change was observed in the hands, face, and chest. For a year there had been increase of thirst and appetite. The urine was passed in excessive amounts and stained the linen. There was considerable loss of flesh and strength. The patient's face was greatly enlarged, particularly in its vertical diameter; the inferior maxilla was prominent; and the lips were thick, particularly the lower. The nose was greatly enlarged, its septum and alæ being quite voluminous. The sternum and clavicles were also increased in size and the breasts were atrophied. Cervico-dorsal kyphosis was present. The hands were enlarged and thickened in both their longitudinal and transverse diameters. The feet were enormous, but the hypertrophy involved especially the antero-posterior diameter. The tongue was greatly enlarged, its surface being marked by elevations and de-

pressions. The mouth was dry and the gums painful. The area of cardiac percussion-dulness was increased. At the base a presystolic murmur was heard, continuing into the systole. The lower extremities were edematous. Tactile, thermic, and painful sensibility were unaltered. Excepting sight the special senses were normal. Vision was impaired, being one-half in the right and one-third in the left eye. The pupils were paretic, in greater degree upon the left; their consensual reaction was preserved. There was found bitemporal hemianopia; but the hemiopic pupillary reaction was not present. There was amblyopic divergent strabismus of the left eye with passing diplopia. The patient passed from ten to twelve quarts of urine daily, containing an ounce-and-a-half of sugar to the quart and traces of albumin.

The Immunizing and Curative Action of the Antitoxic Serum of the Calf Against Typhoid Infection.—BEUMER and PEIPER (*Zeitschrift für klinische Medicin.*, Band 28, Heft 3, 4, p. 320) detail observations showing that animals can be rendered immune to typhoid infection by previous treatment with dead typhoid-bacilli. It was further found that such injections were well borne by a healthy person. Finally eight cases of typhoid fever were treated upon the same lines with favorable results. Further experiments showed that the blood-serum of untreated calves constituted an unfavorable medium for the development of typhoid-bacilli, and that of animals previously inoculated with dead typhoid-bacilli constituted a still more unfavorable medium. It was next determined that animals treated with the antitoxic serum resisted typhoid fever, and that in cases already infected the disease pursued a favorable course. These observers found, as have others, that the typhoid-toxin is largely contained within the bodies of the micro-organisms, and is present in but small quantity in the culture-fluid.

Chronic Gonorrheal Cystitis cured by Influenza.—GOLDBERG (*Centralblatt für innere Medicin*, 1895, No. 26, p. 625) has reported the case of a man, twenty-three years old, in which, following an attack of influenza of ordinary severity, a cystitis of gonorrheal origin of more than a year's duration that had resisted active treatment disappeared.

THERAPEUTIC NOTES.

The Treatment of Diphtheria with the Antitoxin.—SPRINGORUM (*Deutsche medicinische Wochenschrift*, 1895, Nos. 31 and 32) reports that from the middle of August, 1894, to April 1, 1895, 206 cases of diphtheria in children were treated at the City Hospital of Magdeburg with the antitoxin, with 78 deaths, a mortality of 37.9 per cent. At first the treatment was carried out only irregularly, moribund and hopeless cases, as well as those of favorable prognosis, being excluded. Subsequently all children were inoculated that presented involvement of the larynx and evidences of septic intoxication, and also those with an unfavorable prognosis. Of 482 cases of diphtheria treated during the same period without the antitoxin, 122 terminated fatally—25.3 per cent. One-hundred-and-thirteen of the cases treated with the antitoxin required tracheotomy, with 52 deaths—46 per cent., while among the 93 not requiring tracheotomy there were 26 deaths—27.9 per cent. On the other hand, among the cases treated without the antitoxin, 140 cases required tracheotomy, with 78 deaths—55.7 per cent., while 342 did not require tracheotomy, with 44 deaths—12.8 per cent. In addition to the treatment with the antitoxin, applications of cold were made to the throat, and gargles of potassium permanganate and aluminum acetate were employed. Young children received a mixture of ferric chlorid and potassic chlorate. When the deposit was extensive and croupous manifestations were present, inhalations of a solution of sodium chlorid were practised. Diphtheric inflammations of the nose and ears were treated with irrigation, and coexistent bronchitis with expectorants.

According to the monthly report of the Bureau of Health of Denver, Col., it appears that in the eight months since December 1st, when the antitoxic serum became available for use, there have occurred 112 cases of diphtheria, and of the total number 25 died. Of these cases, 37 (all but three being identified by bacteriologic examination) were treated with the antitoxic serum, and of these but three died—a mortality of 8 per cent.; 75 cases (of which not more than 30 were determined bacteriologically) were treated without the antitoxin, and 22 died—a death-rate of 30 per cent.

In the Treatment of Gonorrheal Arthritis, BALGER (*Corresp.-bl. f. Schw. Aerzte*, 1895, No. 15, p. 480) immobilizes the member involved and applies to the affected joint an ointment consisting of

R.—Acid. salicylic.	10
Olei terebinthinæ . .	10
Axungiæ porci	100

After the acute stage has passed and the temperature has not exceeded 98.6° F. for several days, the patient is given baths of ten or fifteen minutes' duration, prepared by adding to the usual amount of water from three ounces to a pint of a mixture consisting of

R.—Olei terebinthinæ . . .	100
Sodii carbonatis	500
Aquæ	1000

Or

R.—Emulsionis saponis viridis . .	200
Olei terebinthinæ	100

Instead of the full bath a local bath containing a proportionate amount of the turpentine-mixture may be employed.

The Employment of Guaiacol as a Local Anesthetic.—LUCAS-CHAMPIONNIERE (*Bulletin de l'Academie de Médecine*, 1895, No. 30, p. 146), having observed distinct relief from pain from the application of an ointment containing guaiacol to a burn, was led to employ the same agent by subcutaneous injection for various anesthetic purposes. The results were eminently satisfactory and unattended with unpleasant features. The anesthesia produced compared favorably with that due to cocain. At first a solution of guaiacol in sterilized oil of almonds was made, but later a solution in oil of olives. The strength of the solution was at first 1 : 10, but later 1 : 20. A syringeful thus contained about 10 centigrams or 5 centigrams, respectively. The mode of procedure is especially applicable in minor surgery. The anesthetic effects are observed in from five to eight minutes after the injection.

THE MILK-QUESTION.

ALTHOUGH the milk-question has probably always been a subject of warm discussion, never has so much been said and written upon it and from so many different points of view as in the last five years. The bacteriologist, the veterinarian, the pediatrist, the chemist, the legislator, and even the philanthropist have busied themselves with the matter; medical journals have teemed with literature pertaining thereto; commissions have been appointed to investigate the milk-supply of cities; many laws have been proposed to regulate the traffic; large industries based upon the deductions of specialists have been put into operation; private charity has been stimulated to establish depots for providing the infants and invalids of impecunious families with pure and sterile milk; and yet the death-rate of children under five years of age shows little or no reduction, and hand-fed babes die in summer now as they did twenty years ago.

We have thought that a short review of the situation as it presents itself might prove of interest if not of value, although we regret that we have no solution of the problem to offer.

First of all, chemists have been engaged upon new analyses of human milk, and find reason to estimate the percentage of albuminous matters at lower figures than have been given in previous formulæ. In the formulæ of König, Pfeiffer, and Leeds about 1 per cent. of albuminoids is given as the amount commonly present. Heubner, Forster, Hoffman, and Johannisen[1] find that the average amount is nearer 1 per cent. than 2 per cent.; Heubner places the figure at 1.05 per cent. and Hoffman at 1.07 per cent. Dr. A. V. Meigs, thirteen years ago, in a paper read before the Philadelphia County Medical Society,[2] contended that human milk never contained more than 1 per cent. of casein. In order therefore to make cow's milk correspond with human milk the proteids will need to be reduced two-thirds instead of one-half, as was the former custom. Wroblewski[3] has studied the nature of the casein of human milk as compared with that of cow's milk and finds that the former contains less carbon, nitrogen, and phosphorus than the latter and more hydrogen and sulphur. That the caseins of the two fluids never behaved alike has long been known, and the failure to sufficiently recognize this fact may account for some of the unsuccessful attempts in infant-feeding attending the substitution of cow's milk for human milk.

Biedert believes that the less digestible casein present in cow's milk constitutes a more favorable medium for bacteria to flourish in. Heubner,[4] however, has not been able to find in the feces of healthy children fed on cow's milk a greater quantity of undigested casein, though he has found a greater amount of other nitrogenous matters.

The importance of milk as a factor in the causation of digestive disorders in the infant has attracted the attention of many medical men, and the literature on the subject is quite voluminous. According to Krisowski,[5] of 1000 breast-fed infants only 7 die from digestive disorders, while of 1000 fed on cow's milk 67 perish from such diseases. Although the chances for living are very poor for the hand-fed babe, the mortality of the first year of life is extremely high for all infants. Erös[6] finds that 44.8 per cent. of all children that die in the first month

[6] Zeitschrift f. Hygiene, B. xix, Heft 3.

of life, die before they are a week old; that 25 per cent. of the first month's mortality occurs on the first day of life, and at least 10 per cent. of the deaths of the first year happen within a month after birth. While noting these facts we must not ignore causes other than those relating to nutrition that affect infants fatally. The children of the poor have a much higher death-rate than the children of the rich. The impure air of closely crowded rooms may affect injuriously a young infant's health as much as improper food. According to Fischl, Epstein, and Eröss, septic infection through the navel is responsible for many of the deaths in the newly born.[1] In such facts as these may be found one of the reasons why improvement of the milk-supply has not as yet been followed by any considerable lowering of the death rate.

Neumann,[2] in his own clinic, finds that the children suffer equally from digestive troubles whether they are fed on milk direct from the cow, so-called country milk, or milk that has passed through the hands of several dealers and is retailed over the counter. His patients are derived chiefly from the poorer classes, and therefore the food is not the only disease-producing factor.

To the very long list of substitutes for human milk there have recently been added several modifications of cow's milk, considered of value by their introducers. Among these is the "Fett-milch" of Gaertner.[3] This retains all the cream, the milk being first diluted with an equal bulk of water and the mixture being placed in a specially constructed separator, which allows one-half of the proteids to pass off with the skim-milk. Only a slight addition of sugar is needed to bring the product up to the required standard. Kehrer, on the other hand, uses a milk-serum obtained by the rennet-ferment, and he claims that in this process the digestible proteids alone are retained. Cream is then added to supply the amount of fat needed. Hempel,[4] in order to avoid the use of cow-milk casein, adds egg-albumin to a mixture of cream, milk-sugar, and water, and claims good results from this "egg-albumin milk." Many authorities prefer skim-milk, with cream added, to the whole milk; and as skim-milk, in the larger dairy-establishments at least, is obtained by means of a centrifugal separator, the product is freed of the dirt that it usually contains after milking.

Much has been said for and against the theory of the infectiousness of milk from tuberculous cows. Very few investigators have ever been able to find the bacilli of tuberculosis in the milk of cows not suffering from disease of the udders. An investigation undertaken by Dr. H. C. Ernst for the Massachusetts Society for Promoting Agriculture, and extending over a period of two years, conclusively showed that cows whose udders were unaffected, yet who were suffering from tuberculosis in other organs, yielded milk in which tubercle-bacilli were found; and such milk when fed to healthy calves rendered them tuberculous. Of 36 cows under examination 12 produced milk in which tubercle-bacilli were detected on one or more occasions, and of 21 healthy calves fed on the milk of these cows 8 became affected with tuberculosis.

When we consider that according to Peters[1] 26 per cent. of 165 herds examined in seventeen North American States were found tuberculous, and that the statistics of German abattoirs reveal the fact that from 10 per cent. to 15 per cent. of all the cattle slaughtered are found to be tuberculous, the danger of infection from the use of milk cannot be overestimated. The laws that have been enacted in several States looking toward the destruction of tuberculous cattle cannot in our estimation be too rigidly enforced, if the results reached by Ernst are at all worthy of acceptance. The experiments themselves are of such a simple nature that the results ought to be speedily confirmed or corrected by other authorities.

Another question that has been the subject of much discussion is that of milk-sterilization. If milk is fatal to young infants because of the bacteria that find in it a favorable soil for development, the destruction of these germs by heat ought to render the product innocuous and harmless. How to destroy the bacteria without injuring the value of the milk has been the problem.

Flügge[2] persists in the statement previously made by him that, in order to destroy the dangerous germs that are likely to infect milk and that cause peptonization, a higher degree of heat than the one used in Pasteurization is necessary, and that for ordinary

[1] To some of these conditions attention has been forcibly called by Crockett in THE MEDICAL NEWS of August 3, 1895, p. 119.

[2] Zeitschrift f. Hygiene, 1894, vol. xvii, part 2.

purposes cooking on a water-bath for ten minutes is as effective as any process of sterilization now in use. On the other hand, many authorities, including Baginsky, Troitsky, and Backhaus, still urge the use of the ordinary Soxhlet form of sterilization, and claim for it that if a perfectly sterile milk is not obtained thereby the procedure is far preferable to cooking and the product is at least much better than raw milk.

Baginsky[1] shows that milk is rendered harmful through three causes: First, from the non-pathogenic germs that set up various fermentations; second, from pathogenic organisms and their toxic products; and, third, from the germs that are present in the intestine of the child and that find in the ingested milk a suitable nidus for the generation of toxins. Sterilization can only partially lessen the dangers from the first and second causes, but it cannot affect the third.

Auerbach[2] considers the application of steam at a temperature of 115° C. and under pressure for a few minutes as effective as any form of sterilization.

Backhaus[3] contends that the advantages of sterilized milk are greater when the milk is prepared in large establishments than when it is sterilized by the consumer; the liability of contamination by frequent handling is lessened and the chances are that the milk is in a fresher condition.

All writers are agreed upon the necessity of keeping the dairy strictly clean. of observing the rules of cleanliness in milking, and in the transportation of milk, cooling the milk immediately after it leaves the cow and keeping it cool until it can be sterilized. Of course, no amount of precaution on the part of those who prepare the fluid will be effective if the sterilized product is exposed in a filth-laden atmosphere by a careless or ignorant mother. Bottles containing just sufficient milk for one feeding are generally advised and are to be preferred to the preparation of milk in bulk.

In many European and a few American cities milk can be had prepared with great care and according to any formula; the dairies are under strict supervision, the milk is carefully guarded from contamination, is examined frequently by chemists and bacteriologists, and is treated according to scientific principles. In Göttingen, Germany, milk is commonly sold for five cents a quart; while carefully prepared "children's milk" can be had for ten cents a quart. Sterilized milk can be bought in Philadelphia, in separate bottles holding eight ounces each, for twenty cents a quart.

Private philanthropy has established "sterilized-milk depots" where good milk can be obtained in sterile and unsterile condition for less than cost. Some of these organizations have been called into existence simply to satisfy a desire for publicity and notoriety, and have met with deserved failure. In other cases lack of technical knowledge, together with business inexperience, have caused the attempt to be abandoned, but most often the expense has been too heavy, and the money that a charitable public was expected to contribute was not forthcoming.

Neumann, of Berlin, and others who have been working among the children of the poor hold that the municipality should take upon its own shoulders the maintenance of suitable dairies and supply the children of the poor with proper nourishment at cost, as it now furnishes its inhabitants with pure water and endeavors to keep the air pure. This is one step further in the line of recent legislation, both in Europe and America, tending to increase the responsibility of the State in preventing disease, and if an improper milk-supply causes the death of thousands of infants, why not endeavor to prevent this waste of child-life by turning dairyman and giving every one the opportunity to obtain the purest and safest milk possible? Such at least are the arguments of those who favor State control. Paris has in connection with one of its municipal crèches a dairy controlled by the municipality, and children's hospitals and foundling-institutions have been urged by various writers to manage their own dairies. France is very desirous of increasing her population, and is endeavoring to do so by preventing waste. Other countries have not yet reached the point where the births per 1000 are less than the deaths, and therefore are not yet so much concerned about the 25 per cent. mortality of yearlings.

If the mammary gland of the human female is becoming atrophied, and infants do not thrive on cow's milk, no matter how carefully prepared or modified, might it not be well to consider what can be done to furnish all infants with their proper food, namely, human milk. If the child can be fed at the breast during the first year of its life the chances are ten to one that it will live be-

yond its fifth year, and that period past, the expectation of life is a pretty good one. Would it not therefore be well for medical men to direct their energies toward bettering or rather increasing the number of human milkers instead of looking for substitutes. If physical reasons prevent a woman from giving suck to her own child, the causes and the means to overcome the obstacles ought to be discoverable.

If, as in many cases, personal convenience is at the root of the trouble, then surely society should be taught its duty, and public opinion be so educated that it will consider it a disgrace and a crime for a woman to refuse to nurse her offspring when she is capable of doing so.

Not only is such an act an unwarranted cruelty inflicted on the infant, but in a large percentage of the cases it is as fatal to the child's life as if it were disposed of in some fouler way. The mother who, because of poverty, abandons her offspring, is sent to the work-house, and the child is taken from her. Is it less culpable for a mother to refuse her infant its proper food when that food is at hand?

If the time and talent now expended in endeavoring to obtain a pure supply of cow's milk were directed to this other question, and the subject freely discussed in the lay press as well as the medical journals, we would have a lessened infant death-rate and the problem "how and what to feed the baby" would not excite so much attention as it now does.

EDITORIAL COMMENTS.

Medical Education in the United States.—The last ten years have shown no diminution in the attendance at our large medical schools, notwithstanding the fact that entrance-examinations are more rigid, that the course has been lengthened in most cases two years, and that the State examinations make the requirements for the practice of medicine more severe.

In some of the schools the total attendance for the last five years has exceeded that of the previous five years by 60 per cent. Dr. Reilly, in the *Journal of the American Medical Association* of January 12, 1895, places the increase in the attendance at 101 medical colleges at 22 per cent., for 1894-95, as compared with previous years.

In many of the announcements that have been issued this year, the adoption of the compulsory four-years' course is heralded. In Philadelphia the Medical Department of the University of Pennsylvania, Jefferson Medical College, and the Woman's Medical College are now four-year schools. The Baltimore Medical College, the College of Physicians and Surgeons of Baltimore, the Women's Medical College, and the Medical Department of the Johns Hopkins University also demand a four-years' course. The Georgetown and Columbian Universities of Washington and the Howard Medical College of the same city have likewise adopted the requirements of the Association of American Medical Colleges. This by no means exhausts the list of four-year schools. We have simply mentioned those that have been most readily accessible. Many Western colleges, as well as Yale and Harvard, are also in line. Only one school in New York State, viz., the Medical Department of Columbia College, has a compulsory four-years' course.

The New York law requires three full years' study, the Attorney-General ruling that this means thirty-six months; yet only three courses of lectures are necessary, so that a student may study with a preceptor eighteen months of the thirty-six and attend college the other eighteen, or even spend less time at an accredited school. The wording in some of the recently issued announcements is rather ambiguous. In accordance with a resolution adopted June 7, 1894, by the Association of American Medical Colleges, attendance upon *four* full courses of instruction, of not less than six months' duration each, will be required of all who intend to graduate in 1899 or thereafter.

Thus in the catalogue of the Western Pennsylvania Medical College, among the requirements for graduation (p. 15), it is stated that the candidate for the doctorate "must have studied medicine for four consecutive years and have taken *three* full courses of lectures." And on p. 14, at the top of the page, it is stated that the time of study required is four years, including *four* full winter terms of lectures. In this college matriculates of 1895 can graduate in 1898.

The Colorado School of Medicine, on page 10 of its announcement, says: "Hitherto the course has been of three years' duration; but students who take their first course of lectures in 1895, or thereafter, must attend four full courses of lectures, no two of which can be taken in the same year;" and on page 25, "all students who enter college on and after September, 1895, must have attended *four* full courses of lectures before they can become candidates for graduation." There is no mistaking the meaning here. The wording of the resolution of the Association of American Colleges would lead one to infer that the four-years' course was compulsory only for those who intended to graduate in 1899, and that those who matriculated in September of this year could graduate in 1898. The greater number of colleges have interpreted this as coming into force this year, and are therefore four-year schools from September, 1895.

The advances along the line of medical education in this country in the past ten years have been truly great, but there is still room for much-needed improvement. First of all must come the abolition of State lines. We must have uniform requirements for admission, uniform requirements for graduation, and uniform laws for registration. The right to practise in one State should carry with it a right to practise in all States. Only then will the American medical diploma have a worthy meaning for our *confrères* abroad. The licence to practise medicine should be a Federal licence, granted by duly appointed Federal examiners; and all colleges should be made to act in conformity with rules established by them.

The Index Medicus.—We desire to call attention to the communication of Dr. John S. Billings, one of the editors of the *Index Medicus* from its foundation, in another part of this issue of the News. As will be seen, the number of subscriptions already reaches 48, and it should be an exceedingly easy matter to make up the guarantee-number of 200. If every medical body in this country with a membership of 25 or more would make itself responsible for one subscription the requisite number would soon be reached. Nor would it be too much to expect all of the medical colleges to do likewise. The question of the continuance of the *Index* is such a vital one, and the needs for its effectuation relatively so insignificant, that it would simply be disgraceful if the present effort should fail. The response to this final appeal should be immediate and liberal.

As to periodicity of appearance of the revised *Index* we think a monthly, as heretofore, would be preferred by most medical literary workers, but a quarterly would probably entail less labor upon the editors and likewise less cost for publication.

The Use of the Clinical Material of the Municipal Hospital for Teaching.—It would be a decided advantage to the medical students of Philadelphia if the clinical material of the Municipal Hospital for contagious diseases was in some way utilized for their instruction. Comparatively few of those who graduate in medicine have the opportunity, as students, to see cases of the exanthemata, measles, varicella, scarlatina, smallpox, and yet when called upon they are expected to recognize such diseases at once, and are often censured for delay or for mistaking them for other maladies.

The great danger to the community from professional ignorance on this subject must be obvious, and the early recognition by the medical attendant of a case of variola or scarlet fever may be the means of preventing a serious epidemic. Under proper precautions it seems to us that members of the graduating classes of the various medical schools could be admitted in small groups to the wards of the hospital and there be shown a few typical cases. The knowledge thus obtained cannot be offset by any didactic teaching, and cannot fail to leave a lasting impression.

Collection of City Garbage.—While there has been a decided improvement of late in the manner of collecting city garbage, owing to the introduction of closed iron carts, yet, the placing of garbage in all sorts of boxes and small buckets on the sidewalks of our city, when the passerby must inhale the odors that such garbage emits, is an evil that ought to be remedied. Often the receptacles are overturned and the contents are thrown into the street, where they lie until cleaning-day. A garbage-decorated sidewalk may have some attraction for the artist, especially at this season of the year, when the coloring is quite varied and rich; but the sanitarian and the ordinary individual would be much better satisfied if the mess were kept covered, out of sight, and out of smell, although not out of mind.

A move in the right direction is the use of public garbage-cans. The lids should be so attached that they cannot be lost, and regular disinfection would probably greatly lessen the offensiveness of the odors arising from decomposing material.

Progress in Medical Education is urged, so far as relates to the Harvard Medical School, by President Eliot, the specific suggestions consisting: first, in the requirement of a degree in arts, science, or letters as an entrance-condition; this requirement to become operative in the year 1900. He also urges the shortening of the college-course to three years. The second change he would advise is the establishing of elective courses in medicine, so that the amplitude of instruction would be such that to take all the possible courses supplied by the faculty a single student would require eight, twelve, or twenty years. The third thing desirable for the Harvard school is a hospital of its own, in order that teachers may have clinical opportunities. We sincerely trust that all the suggestions may be realized, as they are beyond question in the interests of genuine progress.

Orthographic Ignorance, etc.—Our attention has been called to the fact that in the list of words taken from the papers of applicants for the licence to practise medicine and examined recently in Pennsylvania appear the spellings "draft" and "woolen." The list given was furnished by one of the examiners, and these two words were inadvertently permitted to remain, although they have the sanction of the best authority and are preferred by The Medical News itself. In this connection we would also call attention to the letter on "Preliminary Examinations in Medical Colleges," on another page, from an intelligent graduate of 1895, who points out how some of the mistakes in spelling may have occurred, and who also places the blame for some of the failures where it properly belongs.

CORRESPONDENCE.

LONDON LETTER.

The Meeting of the British Medical Association.

The annual meeting of the British Medical Association, which was brought to a close last week, was the largest gathering of that body ever held. The total attendance was not much less than three-thousand, including some two-hundred foreign visitors. This number, respectable as it is, fell considerably short of the expectations of the Executive Committee, who had hoped that at least five-thousand or six-thousand members would have taken the opportunity of combining the *utile* of scientific edification with the *dulce* of entertainments and festivities such as London offers in the season. As it was, the meeting was much larger than the average.

The Association has now thrice held its annual meeting in London—first in 1862, when it numbered only 1500; then in 1873, when its membership had grown to 5400; and now in the present year of grace, when it is 16,000. In its earlier days the Association was for a considerable time on the verge of bankruptcy; now it has assets to the amount of £60,000 ($300,000) beyond liabilities, and an income from its *Journal* of nearly £5000 ($25,000), which, with better management, might easily be doubled. Even in 1873 it was a very unimportant body, with little influence in the profession and none at all in the nation; now through its *Journal* it speaks with a voice that makes itself heard even amid the din of political battle, and through its Parliamentary

Bill Committee it can impress its views on legislators and governments.

By the unanimous testimony of all who were present, the meeting was, both from the scientific and from the social point of view, a distinct success. The gathering was not thrilled by the announcement of any discovery likely to mark an epoch in the history of the healing art, but there were some good discussions, and on the whole the scientific work was, in Bacon's words, "frugiferous," as well as "luciferous." The general addresses were below the average of such discourses. That of the President, Sir Russell Reynolds, was a homily *de omnibus rebus et quibusdam aliis*, atrophic in thought, anemic in expression, loose-jointed in structure, and inaudible in delivery. The "Address in Medicine" (by Sir William Broadbent, the "well-beloved physician" of the Rothschilds and other leaders in Israel) was a mixture of second-hand erudition and first-hand twaddle. The "Address in Surgery" was delivered by Mr. Jonathan Hutchinson, who *more suo* was didactic. He gave an instructive account of the difficulties that ovariectomy and lithotomy had to encounter in gaining a footing in London. Perhaps the most notable part of the address, however, was Mr. Hutchinson's uncompromising declaration that "no one ought now to die of cancer of the tongue, for nothing except neglect of the early stage can bring about such a result." Yet thirty or forty years ago so bold and so skilful a surgeon as James Syme, having had three fatal results in succession after excision of the tongue for carcinoma, was so disheartened that he said he would never attempt the operation again.

In the section of medicine, the President, Dr. Pavy, took for the subject of his opening address "Microbes, Toxins, and Immunity;" he is something of an old fogy, and, having nothing in particular to say, he said it not ungracefully. The section in surgery was opened with a good address on "The Surgery of War," by Sir William MacCormac, whose scalpel has, under the auspices of the Red Cross Society, flashed on many a battlefield. He dealt with the wounds made by the new magazine-rifle bullet, which he does not, like some of our army-surgeons, "regard as a perfect weapon from a humanitarian point of view." In opposition to certain high authorities he holds that in the future wars will be bloodier than in the past. In connection with this matter, it may be mentioned that Surgeon-Colonel William Taylor, of the Army Medical Staff, who accompanied the Japanese army through all the operations of the recent war in the East, has sent in a report to the Government embodying the results of his observations in the field, particularly on this point of the injuries inflicted by the new bullets. The publication of this report is looked forward to with much interest by surgeons, but heaven only knows when it may see the light, for in government departments the period of literary gestation is often indefinitely protracted.

In his presidential address to the Section of Obstetric Medicine and Gynecology, Sir William Priestley (whom Sir William Fergusson once irreverently described as "a fumbler of aristocratic vaginæ") raised his voice against the promiscuous spaying and other surgical atrocities of which women have in recent years too often been the victims. The protest is a little belated, as far as this country is concerned, for there has for some time past been a very distinct subsidence in the epidemic of operative fever that raged in hospitals for diseases of women. Gynecology at one time threatened to degenerate into a form of sport; operators "bluffed" against each other with statistics; they "compiled" their "centuries" as Grace does in the cricket-field, and they strove to break the record of competitors. Owing partly to the force of professional opinion and partly to the recent obscuration of one or two stars of the first magnitude in the gynecologic firmament, this form of sport is less popular than it was a few years ago.

Mr. Ernest Hart, the President of the Public Health Section, in his opening address, cursed the Indian Government for its backslidings in the matter of sanitation with a fervor and a tropical luxuriance of invective that St. Ernulphus might have envied. His theory of cholera is delightfully simple; it is all the fault of a fossilized officialdom that cannot or will not see that the one thing necessary to keep it off is boiled water. The true hygienic palladium is the tea-kettle. This easy means of sanitary salvation Mr. Hart preaches with what Indian officials doubtless consider "damnable iteration," and his vigorously blown trumpet can hardly fail to do good by waking the slumberous authorities to a sense of their responsibilities, not only to India and to Great Britain, but to the nations of the earth.

As to the work of the sections, only a few salient points need be touched on here. The most important discussion was that on serum-theurapeutics in the Section of Pharmacology and Therapeutics. With one exception, all the speakers bore testimony to the great value of the antitoxin-treatment in diphtheria. The one hostile witness, Dr. William Gayton, was, however, an important one, by reason of his position as Medical Superintendent of the Northwestern Fever Hospital, London, where he has had an exceptionally large experience of the disease. He drew an elaborate statistical comparison between the results of treatment in diphtheria-cases in the hospital under his charge during the antitoxin and pre-antitoxin periods, respectively, and he summed up his experience and that of his colleagues as follows: "Those cases that under the old treatment would probably have died were still fatal under the new. Those which might get better recovered in about the same proportion, whilst the mild cases improved no more rapidly—indeed, rather the contrary, considering the frequency of the incidence of rashes, than those without it."

There was an animated debate on the same subject in the Section of Medicine. Here, again, there was a practically unanimous chorus of praise of the new remedy, the one dissonant note coming from Mr. Lennox Browne, who has recently found himself irresistibly impelled by his scientific conscience to publish a book banning the antitoxin, just as he was led by the same internal monitor, soon after Koch's deliverance, to issue a volume blessing tuberculin.

Another important communication was presented to the Section of Medicine by Professor E. Maragliano, of Genoa, who reported the results of a clinical trial of an "antituberculous serum" of his own manufacture. This serum he obtains from dogs, asses, and horses, "by methods different from those hitherto used, discarding absolutely cultures of living bacilli and employing exclusively the highly toxic principles extracted there-

from." This serum he has used in 82 cases of pulmonary tuberculosis of varying degrees of severity. Of these, 61 were more or less benefited, and all of them in which the disease was not too far advanced were either cured or were said to be on the high road of recovery. The serum is administered by hypodermic injection. In apyretic cases it is given in doses of 1 cubic centimeter on alternate days for ten days; then a similar quantity is given once daily for ten days; and, finally, twice daily for a like period. In markedly febrile cases a dose of 10 cubic centimeters is administered at once; then after three days, if there be no recurrence of pyrexia, a dose of from 1 to 2 cubic centimeters is given daily. If, on the other hand, the temperature rises again, a second dose of 10 cubic centimeters is administered a week after the first injection. Maragliano emphatically declared that the injections are never injurious, and he claims that they do good even in the gravest cases, neutralizing the effects of tuberculous infection. The improvement generally shows itself within a fortnight of the beginning of treatment, but sometimes it is not visible for a couple of months. Even when the disease appears to be definitely checked the injections should be continued for at least a month longer, and, by way of precaution, it will be well to inject a dose of 1 cubic centimeter weekly for at least a year after all symptoms have ceased. Maragliano's paper has made a great sensation abroad, especially in his native Italy, but the enthusiasm that it excited here was of a distinctly mild type; familiarity with "cures" for tuberculosis has bred something like contempt of them.

In the Section of Ophthalmology, Mr. T. H. Bickerton, of Liverpool, made a vigorous attack on the Board of Trade for its supineness in regard to the eyesight of seamen. A solid body of evidence was placed before the officials not long ago, pointing strongly to the necessity for greater strictness in testing the vision of the men who go down to the sea in ships, particularly in respect to color-blindness, but nothing has come of it. It is the instinct of our "Circumlocution Offices" to meet such appeals with evasion; meanwhile mysterious collisions occur, like that between the "Elbe" and the "Crathie," which are in all human probability due to defective eyesight in some lookout-man, but which the Board of Trade apparently regards as "visitations of God." The Section passed a resolution "that effect should be given by the Board of Trade to the recommendation contained in the report of the Royal Society," but it is safe to predict that till some royal or official personage is drowned nothing will be done.

The Section of Ethics was a new departure, and it is doubtful whether it has fully justified its existence. Various questions relating to the honor and dignity of the medical profession were discussed, a high moral tone was maintained, and the most edifying sentiments were expressed. It is a pity, however, that men of real authority in the profession were conspicuous by their absence from the meetings of this section, and that the business was left in the hands of a small caucus of busybodies, whose only claim to notoriety is their fussiness and their hypersensitive regard for the commercial interests of the general practitioner. They mean well, but they make the profession, of whose conscience they have constituted themselves the keepers, ridiculous in the eyes of the public.

The meeting, as a whole, was well organized, but the subdivision of the work into fifteen sections led to distinct weakness in several of them; indeed, a good deal of scientific sweetness was, owing to this cause, wasted on the desert air. The multiplicity of sections was doubtless intended as a sop to the Cerberus of specialism; it afforded a convenient means of satisfying the exactions of eminent 'ologists of one kind or another who would otherwise have played the part of Achilles sulking in his tent.

At the general meeting, perhaps, the most noteworthy incident was the reappearance of Mr. Lawson Tait, who, as far as public performances are concerned, has been, as the actors say, "resting for some time." He came forward as the champion of the general practitioner against the dreaded rivalry of the registered midwife. The discussion on this subject was conducted at a very high temperature, which reached its maximum when Dr. Murdoch Cameron, of Glasgow, significantly tapping his breeches-pocket, plainly told the opponents of the legislation for midwives that the be-all and the end-all of the agitation was the question of pounds, shillings, and pence. The antimidwife faction, however, was largely in the majority, and by their votes the British Medical Association stands committed to a selfish and discreditable policy worthy only of a body of petty tradesmen.

Another matter brought forward for discussion was a proposal to enlarge the scope of the Association so as to enable it to take an active part in the suppression of quackery and in the protection of the interests of the profession. There are practical difficulties in the way of such a development, and the ruling powers replied to the advocates of a new order of things with a simple *non possumus*. There is, however, a growing feeling among the members that the funds of the Association, instead of being hoarded up or sunk in bricks and mortar, might be more usefully applied in defending them against official tyranny, blackmailing, "sweating" by clubs and benefit-societies, and unfair and unlicensed competition, and in providing them with a pension in their old age. Whether, even if the Association managed to transform itself into such a mixture of grandmother and guardian angel, it would succeed in satisfying its members is decidedly open to doubt, but it is pretty clear that it will have to do something more for them than it does at present.

In its social aspects the meeting was a great success, though the brilliancy of the festivities was somewhat marred by the coincidence of the Geographical Congress. The annual dinner, which is the chief event of the week from the picnicking point of view, went off very well; the speech of the evening was made by Dr. W. W. Keen, who proved that he might have won fame as a humorist if he had cultivated the art instead of surgery. The absence from the dinner of men of light and leading in the political, literary, and artistic world, and the fact that no special courtesy was shown the Association either by royalty or by the city of London, gave rise to a good deal of comment. The city pleads poverty, and royal personages may not have been approached in the right manner, and, in point of fact, the Executive Committee was distinctly weak as far as social influence was concerned. Perhaps, however, the lack of external adornment is not altogether to be

deplored, as the success of the meeting shows that the medical profession can, as Pitt said literature should do, "take care of itself."

A CASE OF "HOSPITALISM."

To the Editor of THE MEDICAL NEWS,

SIR: Will you kindly give your ideas on the question that has been raised among the medical fraternity of our city as to the professional standing of the gentleman referred to in the accompanying advertisements, taken from this evening's edition of two of our daily evening newspapers? This same physician, whom we shall style "Dr. X.," is the possessor of a diploma signed by the faculty of the Medical Department of the University of Pennsylvania, and is, also, the proprietor of a drug-store, in each window of which one may read the following question addressed in large type to the casual passer-by: "ARE YOU SICK? Will prescribe and furnish you with medicine for one-half dollar." A similar advertisement appears also in the newspapers referred to. To continue the statement of his peculiar practices, he openly and freely consults with homeopaths, calling upon the members of the regular school (who may be willing to assist him) in cases of surgery, in which his extremely limited knowledge and skill compel him to turn for the aid that has thus far always been tendered him, although the very medical society to which these men owe allegiance not many years ago refused to admit their consultant into its membership on the ground of his "irregularities" in the practice of his profession! That I should be compelled to seek an expression of your views on such a question as this may seem at first blush a very needless waste of good ink, as he who runs may read this man's title clearly, and may well think me mentally deficient when seeming thus to question my own judgment, which pronounces this "Dr. X." the veriest quack who plies his wares upon the public streets! And yet, if the majority rules, we, who are in the minority on this question are sadly deceiving ourselves, and are making a most unnecessary struggle to uphold the ethics of our profession, which, we maintain, forbids us from all association with any whose methods are not those of the professional gentleman, and whose instincts are such as to degrade the professional conscience of all who may be willing to affiliate with him.

A new hospital has been recently opened in our city, and in the selection of the staff of physicians the Board of Managers determined upon "Dr. X." as one of those who should be requested to give their services gratuitously to the hospital for a term of two months. In doing this they were well aware that they would be arraying the members of the profession against each other, from a canvass previously made upon the question as to whether the members of the profession would refuse to act were "Dr. X." selected for the place; but as they found a majority who were willing to prostitute themselves to the wishes of the Board for the sake of the notoriety to be gained by an official connection with the new institution, they were willing to force the issue, even asserting their determination to break down every barrier which the Code has erected against just such practices as this, and even presumed to call in question the motives actuating us in our refusal to unite with them in accomplishing their impossible task.

At the last meeting of the ——— County Medical Society I made a special presentation of the position which has been taken in this matter by the physicians of our city, requesting the Society at that time to take official action restraining those who had openly declared their intention of so doing from serving in conjunction with "Dr. X." upon the hospital-staff. A refusal to act upon this point, I claimed, would be regarded by these physicians as a tacit admission on the part of the Society of their right to act in open defiance of the Code, and would be a direct attack upon the life of our organiztion which each member had solemnly pledged himself to maintain. *The resolution to this effect was tabled by an overwhelming vote.* What has been the result? A number of physicians whose standing in the State Medical Society is unquestioned, one of them until recently a member of its Judicial Council, are arrayed against three members of equally unquestioned integrity on a question of ethics, as to whether association with a quack is in consonance with the best and cleanest methods of medical practice. The public, unable to judge concerning the matter, sees only two conflicting parties of the medical body, and casts its vote in favor of the one that supports a public hospital, while it condemns the few whose ideas of ethical procedure in such matters are not regulated by an appeal to selfish interest, but govenred, as they think, by the plain directions of the Code of Ethics of the American Medical Association.

But the hospital has already been opened for the admission of patients. "Dr. A.," who serves first as surgeon thereto, and who said to me that he should not be obliged to have any intercourse with "Dr. X." in his official capacity, figures in this evening's paper as having performed a piece of minor surgery at the new hospital, assisted by the very man whom prior to his going on duty he intended to ignore. "Dr. B.," like "Dr. A.," a member of our County Medical Society, and who has also taken the obligation in a "solemn manner" to "loyally support the Code of Ethics of the American Medical Association," eases his conscience of the burden by saying: "I am a specialist. Why should I refuse to serve, when my duties do not bring me into any association with 'Dr. X.?'" And yet, in a case requiring the oculist's special skill, will he refuse to meet "Dr. X." in consultation when called upon by the latter from the medical ward of the hospital? Why this necessity of "having nothing to do with Dr. X." if he be a man professionally qualified for their association, which is asserted by them at one moment and disclaimed in the strongest terms the next! In their endeavors "to beat the devil about the stump" do they not see in what dilemma they must bring themselves in the end?

Let me conclude this letter by quoting a local item from an evening paper headed "Homeopathic Association Meeting. At the regular quarterly meeting of the —— —— County Homeopathic Association held yesterday . . . . in attendance were ——," and "Dr. X.'s" name heads the list of members present! Now, well may these gentlemen feel a trifle discomfitted who have declared themselves in full accord with the Code of Ethics in associating with a self-declared homeopath upon the staff of the hospital. They have hitherto been loud in their declaration that "Dr. X." is a reputable practitioner, the holder of a diploma from the

University of Pennsylvania, and that we in the feeble minority ought not to refuse to meet him professionally. Will they continue this positive attitude now that the mask has been thrown aside and the man stands revealed, free from all disguise? There are two vacancies remaining, practically three, on the staff of physicians and surgeons of the new hospital, occasioned by the refusal of the obstinate minority to sell their birthright for a mess of pottage. Why not fill them by electing two homeopaths? Surely they have been able to receive one of this Association of the Hahnemannian school, an "allopath" and an advertiser besides, and the addition of several others will not *seriously* interfere with their interpretation of what the Code expects of them in their dealings with their professional brothers. The vital question is, Will the State Society say nay?

"Yours truly,

——— ———."

[We have here such a clear and typical case of "Hospitalism" that we willingly give space to this rather lengthy communication. As we wish to deal only with principles, we have omitted names, details, and signatures. The brutal advertisements cut from the evening newspapers accompanied the letter. As to advice, we would bring the matter before the State Society, with accurate statements and records of the proceedings, and demand an official and authoritative decision as to the right of membership in the State Society of the members of the County Society who voted to table and who continue to associate with an advertising quack. There is no use of compromise or shilly-shallying. The issue would better be met at once. The longer the postponement, the more heroic and desperate must the therapeutics be.—Editor of The Medical News.]

THE REVIVAL OF THE INDEX MEDICUS.

To the Editor of The Medical News,

Sir: I enclose herewith a list of subscriptions to the *Index Medicus*, in accordance with the accompanying form which I have thus far received. This is exclusive of subscriptions sent to Mr. George S. Davis, the former publisher of the *Index Medicus*. When the physicians return from their summer vacation I hope that this list will be largely added to.

Very truly yours,

J. S. Billings.

..... 1895.

The undersigned hereby agrees to subscribe for one copy of the *Index Medicus* for year , at $25 per year, subject to the following conditions, viz.: When 200 subscriptions have been received by the editors the publication is to commence, and on notification of this I will send $25 to them. If, by December 1, 1895, the 200 subscriptions have not been obtained, the attempt to revive the publication will be abandoned.

Address,

Address of editors:

Dr. J. S. Billings,

Dr. Robert Fletcher,

Library of the Surgeon-General's Office,

Washington, D. C.

List of Subscriptions for the Index Medicus received by Dr. J. S. Billings to August 23, 1895.

Albany, N. Y.: Dr. A. Vander Veer.

Baltimore, Md.: Dr. William Osler, Dr. H. A. Kelly, Dr. L. McLane Tiffany, Dr. I. E. Atkinson, Dr. W. S. Halsted, Dr. Henry M. Hurd.

Brooklyn, N. Y.: Medical Society, County of Kings.

Cincinnati, Ohio: Dr. P. S. Conner, Dr. F. Forchheimer, Cincinnati Hospital Library.

Denver, Col.: Colorado Medical Library Association.

Galveston, Texas: Dr. J. P. Johnson.

London, Eng.: Royal College of Surgeons, England.

New Orleans, La.: Dr. S. E. Chaillé, Dr. John B. Elliot, Dr. Edmond Souchon, Dr. Rudolph Matas.

New York City, N. Y.: Dr. G. T. Jackson, Dr. J. S. Thacher, Dr. John A. Fordyce.

Ogdensburg, N. Y.: St. Lawrence State Hospital.

Philadelphia, Pa.: Dr. J. C. Wilson, Dr. William Pepper, Dr. De Forest Willard, Dr. S. Weir Mitchell, Dr. George M. Gould, Dr. H. C. Wood.

Quincy, Ill.: Quincy Public Library.

Richmond, Va.: Dr. Hunter McGuire.

Rochester, N. Y.: Dr. John O. Roe.

Salt Lake City, Utah: Dr. S. H. Pinkerton.

Saranac Lake, N. Y.: Dr. E. L. Trudeau.

Washington, D. C.: Medical Department U. S. Army, 10 copies; Library Surgeon-General's Office, 2 copies; Medical Department U. S. Navy, 2 copies; U. S. Marine Hospital Service, 1 copy.

PRELIMINARY EXAMINATIONS IN MEDICAL COLLEGES.

To the Editor of The Medical News,

Sir: There appeared in The Medical News of August 10, 1895, a list of some one-hundred-and-twenty or more words, furnished by a member of the examining-board representing the Medical Society of the State of Pennsylvania. One point made in the remarks preceding this array of ignorance was that the examinations as to literary ability were too lax upon entering the medical school. The point is well taken. All the medical colleges have raised their course from three to four years; and State examining-boards have arisen to confront the young graduate, requiring that he attain an average of 75 per cent. or be refused a right to practise medicine in this Commonwealth. These, together with the incidental difficulties and expenses, stand in the way of his final step from student into professional life. This is as it should be. But what about the requirements of his becoming a student of medicine, fully matriculated in a regular school? I have before me at the present moment the annual announcement of one of the oldest and highest-standing medical colleges of the United States. The printed condition for admission is that the applicant must show a teacher's certificate or a diploma from some recognized literary or scientific school, or a *satisfactory certificate* from the master of some academy or high school. Then, in italics, the hint is given: *To save time the applicant is advised to bring his certificate with him.* If, as is common, he lacks such certificate or diploma, he finds that it is easy to get an obliging friend to write a *satisfactory certificate*, and he enters the college which is to prepare him for fame and fortune. Of course, one would

think that to be matriculated was a guarantee that one's common education was sufficient to permit graduation, but unfortunately this is not the case, and I have known more than one good, honest, hard-working student to come up for his final examination and be turned down because of poor penmanship and worse orthography. For instance, I knew a man who was to have graduated in 1894, who had an exceptional record with his quiz-masters and who made a fine average on all examinations except two, which were written, and on these he failed. One of those branches was surgery. The candidate went to the professor and asked for an oral examination, confident in his ability to answer any question on the subject that had been taught. The reply from the great professor was, "I will examine you again next year." What gross injustice! Here is a man who had expended his last dollar on his education, and was rejected in the end because of a deficiency the faculty should have ascertained in the beginning. Again, I have repeatedly had no mean scholar, while writing in the quiet of his own home and under no particular mental strain, turn to me and ask how to spell some very commonplace word. If this is so, how much greater must be the difficulty and the liability to lapses during the ordeal and mental strain of a public examination in all the important branches of medicine, and in this particular instance conducted for four days in rooms so hot and ill-ventilated that one member of the class fainted. Therefore, I think that for the bulk of the words misspelled we have abundant excuse other than ignorance, and for the remainder the student is scarcely to be held responsible. Rather place the blame where it should be—upon the heads of the trustees and professors of the medical colleges.

Respectfully, E. Z. B.

NEWS ITEMS.

A Centenarian Surgeon.—At Pesaro, on the Adriatic, Dr. Giacomo Asiari attained his hundredth year on the 29th ult., and a brief biography of him has just been issued by a local colleague, Dr. Carlo Rigoni, with the twofold object of putting on record the career of an interesting professional man, and of establishing, subject to every available check, yet another *bonâ-fide* instance of a centenarian. Dr. Asiari was born at Forli on July 29, 1795, at noon. He studied at Forli, Faenza, Ravenna, and Florence, at which latter school, on June 17, 1821, he received his diploma in medicine and surgery. In 1823 he was called to Spoleto as "chirurgo primario" in the hospital there, and distinguished himself as an able and successful operator. His next appointment was in the University of Macerata, where he filled the post of "chirurgo primario" and reader in human anatomy. This readership he succeeded in getting transformed into a regular chair of anatomy, founding, indeed, a "scuola di anatomia," which was previously non-existent in that seat of learning. In 1829 he was called to Pesaro, once more as "chirurgo primario," and there his clinical duties and the calls of an ever-increasing *clientèle* kept him actively employed for the next thirty years, during which he took rank with the leading men of the city and province, like Count Cassi, Baldassini, Paoli, Petrucci, and Perticari. He attended, among other distinguished patients, Prince Charles Bonaparte when, in company with his brother Louis (afterward Napoleon III), the Prince in alighting from his carriage had gravely injured his knee. In the cholera year of 1855 he rendered invaluable service to the poorer victims of the disease, for which the Pesarese town council awarded him the gold medal of merit. Finally, in June, 1861, he went on the retired list, and the town council, in recognition of his merits as a surgeon and as a citizen, gave him a life pension equal in amount to the salary he drew in office. Dr. Asiari thereupon made over his "armamentarium chirurgicum" to the San Salvatore Hospital, and his fine medical library to the Bibliotheca Oliveriana. Since then he has enjoyed a serene and honored old age, his one complaint being the intercurrent neuritis, to which he has been subject for seventy-eight years.—*Lancet*, No. 3755.

Meetings of Philadelphia Medical Societies:

Obstetrical Society,	1st Thursday of month, Sept.—June.	Sept. 5
Pathological Society,	2d and 4th Thursdays of month, Sept.—June.	Sept. 12

The New Mexico Territorial Board of Health at its meeting, June 19, 1895, adopted a resolution that examination will be required of all applicants to practice medicine in New Mexico who shall graduate after July 1, 1897, from any medical college not requiring preliminary examination of its matriculants, or equivalent evidence of satisfactory general education, and, for graduation, evidence of four years study of medicine and four terms of lectures occuring in four separate years. Meanwhile, the present standard of three years' study, three terms of lectures in three separate years, and preliminary examination of matriculants will be maintained toward all applicants who have graduated since July 1, 1890.

A Medico-legal Congress will be held at or near New York City on September 4, 5, and 6, 1895. It will be open to all students of medical jurisprudence. Quite an imposing array of papers has already been promised.

Dr. Frank Parsons Norbury has been elected to the Chair of Practice of Medicine and Clinical Medicine in the St. Louis College of Physicians and Surgeons.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVII. SATURDAY, SEPTEMBER 7, 1895. NO. 10.

ORIGINAL ARTICLES.

NOTES ON EXAMINATION OF THE URINE.

BY HENRY DICKSON BRUNS, M.D.,

OF NEW ORLEANS, LA.;

PATHOLOGIST TO THE CHARITY HOSPITAL; SURGEON IN CHARGE OF EYE DEPARTMENT, EYE, EAR, NOSE, AND THROAT HOSPITAL.

In the New Orleans *Medical and Surgical Journal* for June, 1890, I published a first series of notes on examination of the urine. At that time, however, I was able to report only a very incomplete analysis of specimens sent to the laboratory between November 7, 1889, and January 1, 1890, because a satisfactory system of sending with the specimens a record of the most important clinical facts had only been put into practice between those dates. Since that time the system has been much improved, thanks to the co-operation of my confrères of the visiting staff, and I am now able to present a complete analysis of all the specimens examined. The clinical statements as to age and the day of the disease on which the examination was made are, of necessity, somewhat inexact, but not enough so to cause any considerable error in our conclusions, I believe, especially when large numbers of cases are considered. Indeed, the present number of cases, which includes those given in the first report, is so large that I offer these materials for thought, with some confidence in their usefulness. I have not refrained from making such comments as the figures suggest, but I would emphasize that these reflections have occurred when the notes were taken, at the laboratory-table.

A uniform method has been followed in examining all specimens. The urine is sent to the laboratory by 9 A.M., in screw-top preserving-jars, especially kept in the wards for this purpose. To the jars are tied manilla tags, bearing a brief synopsis of the clinical history. Immediately on receipt of the urine in the laboratory the reaction and specific gravity are taken, and the fluid is poured into a conical glass to settle for an hour or an hour-and-a-half before slides are made for microscopic examination. In the meantime qualitative tests are invariably made for albumin, for sugar, and for other substances, the presence of which in one way or another we are led to suspect.

The "ring-test" is always used in the examination for albumin, as I am convinced that when properly made it is the surest and most delicate. Albumin makes its appearance in the urine under many forms, and is often accompanied by other substances that either disguise or prevent its usual reactions. In acid urines, if we employ heat alone, we find many specimens in which we fail to obtain coagulation, and the test by boiling the upper portion of a long column of the fluid in a test-tube will lead us into error. The addition, too, of a mineral acid to these acid specimens is a delicate matter; frequently, if more than a trace of nitric acid be added, we fail by producing too high a degree of artificial acidity to obtain the reaction; while other specimens require to produce precipitation the addition of an amount of nitric acid that is surprising, and that would never be persevered in by an inexperienced person. Some acid specimens give a precipitate on the addition of nitric acid in the cold, while others will not, and the amount of albumin present has nothing to do with the result.

I have observed that if a color-reaction (usually reddish or purplish) be produced on the first addition of nitric acid, as a rule precipitation of the albumin is not obtained until continued addition of the acid restores an orange or yellow hue to the fluid. I am not speaking now, of course, of well-understood cases in which positive "greenness" on the part of the experimenter offers an easy explanation of the difficulties, but of instances in which even an experienced clinician is annoyed. Most of these difficulties are caused by the fact that a small amount of albumin can form with a small amount of acid or alkali a soluble acid or alkaline albumin, which is only to be broken up and precipitated by the addition of an excess of nitric acid. There is no doubt, however, that organic chemistry may still find here some profitable employment.

In making the "ring-test," if half an inch of acid be poured into the tube, and two or three times the amount of urine be carefully run down upon it, an exceedingly delicate ring of albumin can be perceived if the tube is held against a dark background with the light falling obliquely through it. When, however, but very little albumin is present, it may be some minutes before the cloudy ring becomes distinct. I believe the importance of this time-element has not been sufficiently insisted upon; indeed, none of these matters is discussed

and dwelt upon in our textbooks with adequate force and clearness.[1]

A case that illustrates the importance of allowing time in making the ring-test has come under my observation while writing this paper. A specimen of urine of acid reaction and specific gravity 1013 was examined for albumin by the ring-test, boiling, and the picric-acid test. The latter tests were extremely doubtful, and I saw no ring on making the first. On microscopic examination I found a few hyaline casts, when I looked once more at my ring-test, and then, one-hour-and-a-half after having prepared it, found a distinct ring. On repeating the test and observing it constantly, I found that *four minutes* elapsed before I could be at all certain of the presence of the albuminous ring. Making the urine alkaline and then testing, nine minutes passed before I could be certain of the ring. The object of making the urine alkaline was to ascertain if a source of error that I mentioned in my first paper (1890) had perchance been present. As I pointed out at that time, the ring-test sometimes fails when the specimen to be tested is very acid, for then, apparently, the acidity at the junction of the urine and nitric acid may be sufficient to hold in solution a small amount of albumin; or, in other words, there may not exist anywhere between urine and acid exactly the degree of acidity requisite to the coagulation of the albumin; the degree is everywhere too high. If the urine be rendered alkaline and the precipitated mucus filtered off, this source of error is removed. Should the amount of mucus be moderate filtration is unnecessary; in a moment or two the cloud of mucus lifts; its lower border is marked by a sharp, fine, white line; below is a little clear zone of urine, and at its lower border, just above the junction of urine and acid, is seen the faint nebulous albuminous ring. Of this point also I have seen no mention in our text-books. These two precautions—time and the degree of acidity—being borne in mind, the ring-test merits every confidence; but when the trace of albumin is minute confirmation is (in the Hospital Laboratory) invariably sought by boiling, followed by the addition of a proper quantity of acid.

If albumin is found, 5 c.cm. of the urine are boiled until all the albumin is coagulated and then allowed to stand in a cylindrical graduate and settle for an hour or an hour-and-a-half, when the amount of *moist* albumin is read off and the percentage calculated. All the percentages given in the tables have been estimated in this way, a rapid method that answers every practical purpose and is as valuable for comparison as any other.

Omitting the 111 cases of 1889 the total number of specimens of urine examined was 2685. The number of re-examinations was 355. The number, omitting re-examinations, was 2330.

White Men. Of the 2330, there were specimens from 1288 white men. Of these 1288 specimens, 592, or 45+ per cent., contained albumin. Of the specimens (592) containing albumin, in 169 it was accounted for by contained pus or blood. There were then 592 containing albumin and 169 containing pus or blood; making 423 specimens from cases of presumably pure renal albuminuria, viz., 32+ per cent. of 1288 and 71+ per cent. of 592.

White Women. Of the 2330, there were specimens from 463 white women. Of these 463 specimens, 218, or 47+ per cent., contained albumin. Of the specimens (218) containing albumin, in 97 it was accounted for by contained pus or blood. There were then 218 containing albumin and 97 containing blood or pus; making 121 specimens from cases of presumably pure renal albuminuria, viz., 26+ per cent. of 463 and 55+ per cent. of 218.

Negro Men. Of the 2330, there were specimens from 470 negro men. Of these 470 specimens, 303, or 64+ per cent., contained albumin. Of the specimens (303) containing albumin, in 68 it was accounted for by contained pus or blood. There were then 303 containing albumin and 68 containing pus or blood; making 235 specimens from cases of presumably pure renal albuminuria, viz., 50 per cent. of 470 and 77+ per cent. of 303.

Negro Women. Of the 2330, there were specimens from 109 negro women. Of these 109 specimens, 68, or 62+ per cent., contained albumin. Of the specimens (68) containing albumin, in 28 it was accounted for by contained pus or blood. There were then 68 containing albumin and 28 containing pus or blood; making 40 specimens from cases of presumably pure renal albuminuria, viz., 36+ per cent. of 109 and 58+ per cent. of 68.

We note that the percentage of renal albuminuria is higher among the negro men (77 per cent.) than among the white men (71 per cent.) and among the negro women (58 per cent.) than among the white women (55 per cent.); and that the percentage of cystitis (pus and blood) is higher among the white women (45 per cent.) than among the

[1] Since writing the foregoing, Professor Long's Laboratory Manual of Elementary Chemical Physiology and Urine Analysis, Chicago, E. H. Colegrove & Co., 1894, has appeared, in which all of these are stated with admirable brevity and point. Professor Long notes (p. 191) the importance of the time-element in making the nitric-acid contact-test, but he falls into error when he advises "to set the tube aside for twelve hours, and then observe it." If the amount of albumin is small and the ring delicate, it will, even after the lapse of an hour or two, have disappeared by diffusion or resolution. The suggestion of Professor Long that nitric acid be well warmed before the urine is run down upon it is an excellent one, as by this means we are exempted from chance of error by the precipitation of urates; this error, however, is readily obviated by a little experience and accurate observation; but I cannot agree with Professor Long when he says (p. 193) that the formation of a ring of crystalline urea nitrate "is a very unusual reaction." In my experience it has proved rather common.

white men (29 per cent.) and among the negro women (42 per cent.) than among the negro men (23 per cent.).

TABLE NO. 1.

Ages of 859 cases of renal albuminuria:

		Per cent.
From 5 to 10 years,	5 cases	½—
10 " 15 "	84 "	9+
25 " 30 "	77 "	8+
30 " 40 "	146 "	17—
40 " 50 "	173 "	20+
50 " 60 "	162 "	18+
Over 60 "	158 "	18+
Age not reported in	54 "	6+
Total .	859	

TABLE NO. 2.

Number of times and percentage of occurrence of renal albuminuria at different ages in 1686 suspected cases:

Total No. of cases.	Cases of renal albuminuria.		Percentage.
12.	From 5 to 10 years,	4=	33+
228.	" 10 " 15 "	62=	27—
225.	" 25 " 30 "	61=	27—
291.	" 30 " 40 "	94=	32+
343.	" 40 " 50 "	135=	39—
303.	" 50 " 60 "	122=	40—
257.	Over 60, "	30=	50—
27.	Age not reported,	12=	44+
1686			

Neither race nor sex seems to influence the age at which renal albuminuria most commonly occurs. The percentage rises abruptly at thirty years of age, and in men and women, whites and blacks, the majority of the cases occur during the thirty years from thirty to sixty. Table No. 1, therefore, is made to include the whole 819 cases of 1891–92, together with the forty cases of 1889. For similar reasons Table No. 3 is made to show the amount of albumin, the reaction, and the specific gravity in the whole number (859) of cases.

TABLE NO. 3.

Reaction and specific gravity of 859 cases of renal albuminuria:

Amount of albumin (moist).	Number of specimens.	Reaction			Specific gravity.		
		Neut.	Acid.	Alk.	Max.	Min.	Average.
Trace .	364	11	331	22	1031	1000	1013+
1– 5 p. ct. .	132	2	124	6	1029	1001	1011—
6–25 p. ct. .	244	4	230	10	1032	1002	1013+
26–50 p. ct. .	67	1	59	7	1030	1004	1014+
50 p. ct. or over .	52	2	48	2	1034	1006	1015+
	859	20	792	47			

TABLE NO. 4.

Association of casts with various amounts of albumin in 859 specimens from cases of renal albuminuria:

		Percentages.				
Variety of casts.	Trace.	1 to 5.	6 to 25.	26 to 50.	50 and over.	
Epithelial .	5	1	7	1	1	15
Granular .	37	37	78	22	20	194
Hyaline .	126	55	104	31	29	345
Waxy . .	0	2	1	1	2	6
Total .	168	95	190	55	52	560
No casts .	196	37	54	12	0	299
Grand total	364	132	244	67	52	859
Percentage of occurrence of casts .	46+	71+	77+	82+	100	65+

The average specific gravities corresponding to various amounts of albumin are interesting. With only a trace of albumin in the urine, the kidneys, it may be supposed, being but slightly affected, the specific gravity is about normal; when the amount of albumin increases to from 1 to 25 per cent., the kidneys being, presumably, more profoundly damaged, the specific gravity falls a little; but when the amount of albumin rises to from 25 per cent. to 50 per cent. or over, it, by its very presence, causes a decided rise in the specific gravity. In the fifty-two cases in which the albumin amounted to 50 per cent. or over the specific gravity was never less than 1006. A consideration of Table No. 3, however, and the fact that in 401 specimens of normal urine the specific gravity varied from 1001 to 1028, show conclusively how futile it is to hope for any indication of the presence or absence of albumin from the specific gravity of a specimen of urine.

In Table No. 4 an attempt is made to show the relation between the amount of albumin and the kind of casts found, the number of times per centum that casts were present with each amount of albumin being given. It must be carefully noted, however, that whenever granular and epithelial casts were found together, the kind is set down in the table as granular, and that when hyaline casts were found associated with other casts the kind is always set down as hyaline.

If we take it to be a general rule, and to this all experience inclines us, that disease of the kidney is to be feared only when (after repeated examinations) we find albumin associated with casts in the urine, then Table No. 4 furnishes two valuable indications. First, if not employing the microscope, we make a chemic examination, and a qualitative one only, and determine the presence of albumin, though it be but a trace, the chances are about equal; second, if unsatisfied, we proceed to determine the percentage of moist albumin, and find it to be about 1 per cent., the chances are in favor of renal disease; if between 1 and 50 per cent., the chances are more than 2 to 1; while when the percentage reaches or exceeds 50 per cent., we may feel almost certain that grave renal disease exists. Obvious causes,

like the presence of pus or blood, are of course not taken into consideration.

TABLE 5.

Duration of the disease at the time of the examination, with the amount of albumin and the kind of associated casts in 819 cases of renal albuminuria.

Duration of disease.	Albumin.						Casts.					Percentages.
	Trace.	1 to 5 per cent.	6 to 25 per cent.	26 to 50 per cent.	Over 50 per cent.	Totals.	Epithelial.	Granular.	Hyaline.	Waxy.	Totals.	
Less than 1 mo.	64	12	34	10	11	131	2	25	61	0	88	67+
From 1 to 6 "	150	55	102	31	28	365	7	89	147	4	247	67+
6 mo. to 1 yr.	46	9	24	10	4	93	0	22	42	0	64	68+
1 to 2 years,	21	7	19	1	5	53	1	12	23	1	37	69+
2 to 3 "	17	3	10	1	0	31	1	5	9	1	16	51+
3 to 4 "	12	2	10	2	0	26	1	10	8	0	19	73+
4 to 5 "	4	3	0	1	0	8	0	2	4	0	6	75+
Over 5 "	4	4	2	0	0	10	0	3	4	0	7	70+
Not reported,	39	21	30	8	4	102	0	17	38	0	55	
	357	116	230	64	52	819	12	185	336	6	539	65+

In Table No. 5, it should be called to mind, the duration of the disease given rests solely upon the statements of the patients themselves and is therefore, of course, not absolutely reliable, especially in the case of hospital-patients like these. Nevertheless the number of cases considered is so large that I do not believe serious error has crept in, though the fall to 51 per cent. of casts associated with albumin in cases having a duration of between two and three years is unaccountable and suspicious. Only 819 cases are embraced in this table, as this information could not be had about the 40 cases of 1889.

Turning to the very interesting question of the symptoms associated with renal albuminuria (Table No. 6), I must confess that I do not think these were reported as the result of any careful study of the cases, and in so far they are untrustworthy, doubtless; but they have an interest as the most striking symptoms noted in what was probably an early, incomplete, and hurried examination of a large number of cases by a large number of practitioners of varying ability; *i. e.*, the average "first visit" of the average "busy practitioner."

TABLE NO. 6.

Résumé of symptoms reported at least fifty times, together with percentage of association of the symptom with casts:

Symptoms.	Total cases.	Percentage.
Edema of extremities	423	67+
Anasarca	227	73+
Dyspnea	212	72+
Edema of face	167	64+
Headache	141	61+
Dizziness and dimness of vision	79	63+
Heart-lesion	77	66+
Scanty urine	66	66+
Frequent urination	52	44+
Anemia	57	68+

Regarding only those symptoms, mentioned at least fifty times, it was found that anasarca, dyspnea, and anemia were most frequently associated with the presence of casts, while frequent micturition was far less often so associated. If then this table is fairly trustworthy, the limitations already noted being kept in mind, the presence of anemia, dyspnea, and anasarca should at once suggest the likelihood of true renal disease, while frequent urination should rather direct our attention to the genito-urinary apparatus. Of course, there is nothing surprising in this, but it is interesting to see it supported by actual figures and percentages.

Casts were found in 40 specimens (out of 2441 first examinations of 1889, 1890, 1891, and 1892) that contained no serum-albumin.

Thirty (30) of the 40 specimens were from white men; one (1) was from a white girl; seven (7) were from negro men; two (2) were from negro women.

The ages ranged from 8 to 80 years; the duration of the disease varied from three days to three years; the specific gravity from 1002 to 1035; the reaction was acid in 19, alkaline in 2, and unrecorded in 19; the casts were hyaline in 14 instances, granular in 4, epithelial in 1, and unrecorded in 21. The symptoms recorded were edema, headache, scanty urine, bronchitis, anemia, backache, frequent micturition, dimness of vision and dizziness, dyspnea, anasarca, emaciation, heart-lesion, pregnancy, diphtheria, and uremic convulsions. It is highly probable, of course, that albumin was escaping in some one of its many forms other than serum-albumin, but as the latter is the form almost invariably tested for by practitioners the occurrence in these cases of "casts without albumin," to the number of 1 to every 61 specimens examined is of interest and importance.

Sugar. Sugar was found in only 12 of the 2330 specimens, and was associated with albumin (from a trace to 5 per cent. moist) in only four. The reaction was acid in every instance and the specific gravity varied from 1022 to 1048. The ages of the patients ranged from 7 to 49 years; 10 were males and 2 females, while 10 were whites and 2 blacks.

TABLE 7.

Other abnormal or unusual constituents found in specimens free from albumin, casts, or sugar, in a grand total of 2441 first examinations of the urine.

The 2441 specimens were from

Men	1835	Whites	1831
Women	606	Blacks	610
	2441		2441

	Age.			Sex.		Race.			
	5 to 20.	21 and over.	Not reported.	Males.	Females.	White.	Black.	Not reported.	Total.
Spermatozoa	1	27	4	31	1	28	4	0	32
Red blood-corpuscles	3	82	31	86	30	86	30	0	116
Urates	6	55	7	53	15	46	19	3	68
Uric acid	7	64	10	58	23	63	18	0	81
Calcium oxalate	5	111	5	93	28	96	25	0	121
Phosphates (triple)	7	43	10	38	22	43	17	0	60

Table No. 7 includes the 111 first examinations of 1889, as well as the 2330 of 1890-91-92, a total therefore of 2441.

Columns cannot be added, as these constituents were often found associated in the same specimen.

Concerning the urinary sediments, I have but a single note to make. The so-called dumb-bell crystals of calcium oxalate do not, I am convinced, exist. These forms are, in reality, all biconcave discs, of greater or less regularity and exactness of shape, and are connected by transition-forms of infinite variety with the classic octahedra. The various forms are depicted with great exactness on page 329 of Professor Long's recent work, save that in the supposed typical dumb-bells the fine contours defining a biconcave disc, as in the red blood-corpuscle seen in profile, can, I believe, be always made out by suitable illumination and exact observation. It is proper to note here that crystals of triple phosphate may often be found on making the microscopic examination in a urine having a (general) acid reaction for the following reason: The sediment that settles at the bottom of a conical glass, after the urine has been standing for an hour or so, is that portion always collected for microscopic examination. Now, while the upper portions of the urine still show a decidedly acid reaction, the extreme lower portion, the few drops at the conical bottom of the collecting vessel in which all the sediment is contained, may have become alkaline and be fairly loaded with crystals of triple phosphates. Some emphasis is to be laid upon this point, as the clinician is likely to look askance upon a report giving the reaction of the urine as acid, and yet mentioning crystals of triple phosphate as constituents of the microscopic sediment.

TABLE 8.

Symptoms (reported at least twenty times) occurring with unusual or abnormal constituents in specimens of urine free from albumin, casts, and sugar.

	Spermatozoa.	Red blood-corpuscles.	Urates.	Uric acid.	Calcium oxalate.	Triple phosphates.	Totals.
Anemia	2	6	4	5	8	2	27
Anasarca	1	8	11	4	10	3	37
Backache	3	8	5	11	14	3	44
Dizziness and dimness of vision	3	7	8	5	12	4	39
Dyspnea	2	11	9	4	19	9	54
Headache	7	18	13	14	33	11	93
Heart-lesions	0	3	5	3	6	2	21
Edema of face	3	10	6	3	9	4	35
Edema of extremities	13	39	18	23	58	23	174

Finally, as I have noted under Table No. 8, I found the average specific gravity of 401 specimens, in which the reaction was normal and nothing unusual or even noteworthy to be found, to be 1012 +; *i.e.*, between 1012 and 1013. Müller (1840) gives the mean specific gravity as from 1015 to 1020; Draper (1858) as 1020; Carpenter (1864) cites Prout as giving 1020; Simon 1012; Roberts from 1001 to 1036; Kirke (1873) gives 1020; Herman (1878) from 1005 to 1030; Foster (1880) 1020; Landois and Stirling (1886) from 1015 to 1025; Yeo (1888) from 1015 to 1020. The morning urine is said by all to be the heaviest, but this was the urine furnished me in every instance. The lowest specific gravity found among the 401 specimens was 1001 and the highest 1828.

Normal Specific Gravity. The average specific gravity of 401 normal specimens was 1012 +. The lowest was 1001; the highest 1028.

TREATMENT OF LEUKOMAIN-POISONING.

BY B. K. RACHFORD, M. D.,
OF CINCINNATI, O.;
PROFESSOR OF PHYSIOLOGY AND CLINICIAN TO CHILDREN'S CLINIC, MEDICAL COLLEGE OF OHIO.

IN previous papers[1] I have shown that paraxanthin and other leukomains of the uric-acid group are etiologically related to true migraine and kindred diseases, such as migrainous epilepsy and migrainous gastric neurosis. For the etiology and symptomatology of these diseases the reader is referred to these papers, as it is my purpose in this communication to speak only of the treatment of these conditions.

The outline of treatment that I shall present is one in which I have learned to have much confidence and one that I am anxious to submit to the judgment of medical men everywhere, in order that I may the more quickly determine its value and its limitations.

The medicinal treatment is the important and indispensable part of the treatment and consists of two prescriptions, which are used simultaneously:

Take—Potassium permanganate . 20 grains.
Make 20 pills and coat with salol.[2]
One of these is to be taken three times a day one hour after meals.

Take—Sodium salicylate . . 2 drams.
Dry sodium phosphate . 4 "
Dry sodium sulphate . 10 " —Mix.

A teaspoonful, more or less, is to be taken in a glass of seltzer-water each morning.

The foregoing prescriptions can be given continuously for months at a time. In one case in which the treatment was eminently satisfactory I continued this treatment without a single day of interruption for four months. I am not sure that it is necessary to have the pills of potassium perman-

[1] THE MEDICAL NEWS, Phila., May 26 and October 3, 1894, and Transactions of the Association of American Physicians, vol. x, 1895.

[2] Mr. Bange, a pharmacist, uses the following formula for coating the pills with salol: Salol, 4 parts; shellac, 1 part; alcohol, 40 parts.

ganate coated with salol, as I believe I have gotten the same good results with the uncoated pills. I have used the salol-coated pills on the theory that this coating would enable the potassium permanganate to pass through the stomach and be dissolved in the small intestine, and in this way act as an intestinal antiseptic. But the special purpose for which it is given is to neutralize poisonous leukomains circulating in the blood. (See previous papers.)

In the second prescription it is important to have pure salts of sodium. These salts will not be so unpalatable if taken in cold seltzer-water. The seltzer-water can be obtained in siphon and used as directed. It is not an important part of the treatment, and is used for the most part to make the "salts" more palatable. Water may therefore be substituted for the seltzer-water without, in any way, detracting from the efficacy of the treatment. In this prescription the quantities of the three sodium-salts may be changed to suit individual cases, the formula as given being the one that I almost invariably use, and I have rather preferred to vary the dose to suit individual cases than to rewrite the prescription with the quantities of the ingredients changed.

When there is considerable constipation it is necessary to give a heaping teaspoonful of the salts to produce the cathartic action which is necessary in the treatment of these cases. If a small dose of salts produces excessive catharsis, the dose may be diminished or the prescription rewritten with less of sodium sulphate and more of the phosphate. But I have often noted that the gouty diarrhea, which many of these patients have, is cured rather than exaggerated by these salts. The "salts" should be given every morning for a considerable period of time.

The relief that follows the treatment outlined is immediate. It is a common experience for patients not to have a single so-called "nerve-storm" after being put upon it. It will often accomplish remarkable results without the aid of any dietetic or hygienic treatment.

The dietetic treatment is very important and should always be adopted as an aid to the medicinal treatment. The diet to be observed is as follows: Fresh meat once a day, with fish, eggs, milk, fruit, and vegetables. I ordinarily direct the patient as to what he should not have, telling him to avoid beer, wine, meat-soup, and meat, except one piece of fresh meat at dinner. Apart from this he may have anything he wishes within the limits of his digestive capacity. Not infrequently the medicinal treatment already outlined very much widens the range of the digestive capacity of the patient, so that he can eat freely of many fruits and vegetables which previously he had learned to fear.

The hygienic treatment is also important in many cases and consists simply of a warm alkaline bath each morning and plenty of exercise in the open air. I usually direct the patient to take a warm alkaline bath as soon as he arises in the morning, and the bath should, when convenient, be followed by an alcohol rub. A handful of sodium bicarbonate and one of sodium chlorid thrown into an ordinary bath-tub of hot water will make the water sufficiently alkaline. The alkaline bath has not appeared to me to be necessary in the treatment of migrainous conditions, and it is not my routine to prescribe it under these conditions; but I have found it a very useful, if not a necessary, adjunct to the other treatment in certain so-called gouty conditions of the muscles and joints. A discussion of the manner in which the alkaline bath produces good results is not within the scope of this paper.

Exercise in the open air is always a valuable aid in the treatment, but it is by no means always practicable, and it is, therefore, well to know that excellent results may, as a rule, be obtained without it. Many cases are, in the beginning of the treatment, physically unable to take open-air exercise, and many of them are confined to hospitals and other institutions where this phase of the treatment cannot be very satisfactorily carried out.

In the foregoing outline I have not attempted to write a complete chapter on the treatment of leukomain-poisoning, but only to call attention to a line of treatment that I believe to have some specific influence in the treatment of this condition. This treatment can be combined or alternated with any other, as the individual case may demand. The conditions that I believe can be benefited or cured by this treatment are as follows:

1. *True migraine*,[1] which I believe to be a form of leukomain-poisoning, can almost certainly be relieved by this treatment. In these cases the treatment should be kept up uninterruptedly for from four to six weeks, and then every other week for from four to six weeks longer, and after this for one week in every month for a few months, when diet and exercise may be depended upon to complete the cure. I have now under treatment ten cases of migraine, all of which have been completely relieved of their paroxysmal attacks, as the following illustrative cases will show:

Case I.—Mrs. G., aged thirty-five years, the mother of two children and the wife of a laboring-man, is a hard-working German woman, who has suffered from sick-headache ever since she can remember. During the past few years she has had an attack almost every week. These attacks would send her to bed, and keep her there from twelve to thirty-six hours. On her sick-headache days her husband would have to cook and do the housework.

[1] Loc. cit.

On May 10th this woman was placed under treatment, and this has been continued, as already described, to the present time (July 25th). This case had only the medicinal treatment, no dietetic or hygienic treatment being attempted. Since this treatment was begun she has not lost a day from work, has not had a paroxysm of sick-headache, and has never been so well since she can remember.

CASE II.—Mrs. E., a German woman, thirty-three years of age, is a meat-eater and beer-drinker. Her mother and one of her sisters have migraine, and she is and has been for many years a great sufferer from the same disorder, having an attack about every two weeks.[1] She was placed under treatment on April 20th, and the treatment has been continued till the present time (July 25th) without a single paroxysm of sick-headache, and during this period she has been for the first time in many years perfectly well.

CASE III.—Mrs. M., aged thirty-five years, has had an attack of migraine about every two weeks for many years. During the past few years these attacks have been so severe that life had become scarcely worth the living. The attacks always come on at the menstrual period, and as a rule once in the intermenstrual period.[2] She has been under treatment from April 4th to July 25th, and during this time she has been free from headache and quite well.

2. *Migrainous epilepsy*, which I have demonstrated to be a form of leukomain-poisoning, can always be benefited and often cured by the treatment already detailed. This disorder, which I have fully described in my previous papers,[3] is a form of epilepsy that occurs as a sequel to migrainous headaches of former years, or the epileptoid attacks may at times take the place of or alternate with the migrainous headaches. It is my belief that many of the cases of so-called hystero-epilepsy belong to this class, and can therefore be either benefited or cured by the treatment. In migrainous epilepsy the treatment should be continued somewhat longer than in true migraine, and the potassium-permanganate prescription is, I believe, of prime importance in the treatment of these cases. My experience with this type of cases, however, has not been sufficient for me to judge of the value or limitations of the treatment. I have a number of such patients under my care at the present time with every promise of success from the treatment, but they have been under observation for too short a time to justify any conclusions as to permanent benefit to be derived from the treatment. The following case will illustrate:

CASE IV.—Miss F., thirty years of age, has a neurotic family history. She is a fairly well-nourished girl, with no evidence of mental impairment. She has had sick-headache since she was a child, and during the past six or seven years she has occasionally had epileptoid attacks instead of the migrainous headaches. These epileptoid attacks have been growing more frequent of late, so that at the present time she never fails to have one at her menstrual period, and not uncommonly one in the intermenstrual interval. The migrainous headaches have also continued, and rarely does the woman pass a week without remaining in bed one day on account of an attack. Formerly the attacks of sick-headache always came at the menstrual as well as during the intermenstrual periods, but now the menstrual headache replaces the menstrual epilepsy. The attacks of epilepsy are usually followed by some headache, but not by the nausea and vomiting that accompany the attacks of true migraine. The urine of this patient passed during and immediately after an attack of migrainous epilepsy and migrainous headache contained paraxanthin and xanthin in great excess.

The treatment was the same as has been outlined, and commenced on May 23d. The woman has passed two menstrual periods without a symptom of epilepsy, and with the exception of one slight attack of headache she has been quite well to the present time.

3. *Leukomain gastric neurosis* is a well-known form of migrainous disease that I have described in a previous paper, in which I gave the evidence upon which I based the conclusion that this was one of the manifestations of leukomain-poisoning.[1]

CASE V.—Mrs. P., aged thirty-four years, is the mother of three children. She had "always been a sufferer from sick-headache" up to November, 1894. At that time frightful gastric attacks took the place of the migrainous headaches. These gastric attacks were very sudden in their onset, and were attended with great pain and with vomiting of mucus. They continued with increasing fury till relieved by hypodermic injections of morphin. They recurred about every two weeks till, during March and April, they were so frequent and so severe that the patient was in bed more than half the time.

On April 15th this patient was placed on the treatment that has been outlined in this paper, and it has been continued up to the present time (three-and-a-half months). During this period the patient has not had the slightest symptom of leukomain-poisoning.

The result in this case was truly remarkable, and never have I seen the treatment of any disease followed by more specific results. For this reason I wish especially to ask for a trial of this treatment in cases of leukomain gastric neurosis.

[1] For a full history of this case, see THE MEDICAL NEWS, November 3, 1894, under the heading "Specimen No. 7."

[2] For a full history of the etiology and symptomatology of these attacks, see Transactions of the Association of American Physicians, vol. x, 1895.

[3] Loc. cit.

[1] For a full description of the etiology, symptomatology, and course of this phase of leukomain-poisoning, the reader is referred to my article in the Transactions of the Association of American Physicians, vol. x, 1895, where the case of "Mrs. P." is given with careful detail.

4. *Hypochondriasis and neurasthenia* in patients having a gouty inheritance are often entirely relieved by the treatment already given.

Case VI.—Mr. R., a middle-aged man, who had always been a good liver, came to my office last May to get relief from more or less constant pain in the abdomen. He was mentally depressed and so despondent about his condition that he could not be convinced but that he had some incurable abdominal disease. He was moody, irritable, and peevish, and did not think that medicines would do him any good. Knowing that there was a strong gouty tendency in this man's family I prescribed the treatment outlined, and he so promptly recovered that in three weeks he was entirely well.

5. Constant headache, sciatica, and intercostal and other neuralgias when occurring in the gouty can very commonly be relieved by the treatment described.

Case VII.—Mr. S., aged fifty years, has been a great sufferer from myalgia and neuralgia for years. About five years ago he had an attack of acute gout, and since then he has had several very severe and prolonged attacks of "muscular rheumatism." When he sent for me he had been suffering from an attack of sciatica and intercostal neuralgia for about two months, which had persisted in spite of good medical attention. This man entirely recovered after one month of treatment. The dietetic and hygienic treatment was as carefully looked after in this case as the medicinal.

Case VIII.[1]—Mrs. Y., aged thirty-seven years, has for years suffered from severe headache accompanied by nausea and sometimes vomiting. During the past nine years these attacks have occurred every two or three weeks, and have very often been so severe that the phenacetin and codein that she is accustomed to take gave her little relief.

On June 15th she was suffering from a headache that had continued almost uninterruptedly for three weeks; she had no nausea and no vomiting in this attack. Codein and phenacetin, of which she had taken a great deal, gave her only temporary relief. At this time Dr. Jones mentioned the case to me, and I advised the medicinal treatment described in this paper. This was done, and two days later the headache had ceased and the patient's general condition was very much better. The treatment was continued for a short while, and up to the present time (July 29th) the woman has remained quite well.

In this communication I have not attempted to give a clinical picture of every phase of leukomain-poisoning in which the treatment here detailed may prove beneficial, but have only sought to indicate the class of morbid conditions in which benefit may be expected from it.

Of the value of this treatment in articular gout I am not prepared to speak, although I have published evidence that the leukomains play a part in this disease. It is also my belief, founded upon the evidence given in previous papers, that many so-called uremic manifestations, including eclampsia, are in great part due to paraxanthin-poisoning, and for this reason I think that potassium permanganate given hypodermically might be of value in the treatment of puerperal and other eclampsias of uremic origin. I shall be under obligations for clinical reports on this treatment.

323 Broadway.

WHAT SHALL WE DO WITH THE OLD WELL?

By HARVEY B. BASHORE, M.D.,
of West Fairview, Pa.

Just about one-third of the population of the Eastern States, and a great part of the population of the whole country, depend upon shallow wells for their supply of drinking-water. That these old wells will transmit disease is no longer to be doubted, and the fact is established by practical experience. Cesspools and privies have almost everywhere grossly contaminated the soil, and, as a well drains a cone-shaped area, the diameter of whose base on the surface is anything from one-hundred to two-hundred times the depth of the well, it is almost invariably placed within the drainage of one of these filth-bearing spots. When conditions are such as these, is it any wonder that well-water transmits disease? Rather a wonder is it that the result is no worse. For instance, a passing stranger or a visitor, ill with diarrhea, stops in a town. The discharges, loaded perhaps with typhoid-germs, are thrown into a privy-vault, or, what is worse, are buried a foot or so beneath the surface of the adjoining garden. In the fulness of time these germs have passed into a neighboring well, and numbers of the community suddenly become sick. Or it may be that milk-cans washed with this water carry the fatal germs to a neighboring hotel. It is the old, old story, and Providence gets the credit in place of human negligence.

I just happen to think of one small town in Pennsylvania where sixty out of eighty inhabitants became ill of typhoid, and eight died—all because they had drunk infected well-water. A strange thing, too, frequently noted is that the most popular well in a district is likely to be the one most contaminated. This is probably due to the fact that the constant pumping consequent upon its popularity keeps the water at so low a level that the drainage of the well is increased; for the ground-water tends to maintain a certain level, and a diminution at any one point increases the drainage about that point.

Although many epidemics have been traced to the use of old wells, there might be many more, were it not for the fact that the infectious diseases

require a specific germ for their origin, and until that is introduced contaminated well-water counts for little as a direct disease-producing factor; but let a colony of germs gain a foothold in one of these filth-bearing places, and their growth, development and propagation are simply matters of time. Let us take, for example, an old well at the corner of New Haven Green. For years this has been receiving the drainage of a filth-laden soil, but we have yet to hear of its being counted a factor in disease. Yet, who can tell at what moment fatal germs may find a lodgment? Surely he who drinks of this water has a two-edged sword over his head of which he never dreamed.

Still there are hundreds of just such wells scattered through the country, simply waiting to become infected; but only typhoid breeds typhoid, and for the moment we are perhaps safe; but, after all, we are not so safe as we may imagine, for it has been found that polluted water, although not directly causative of disease without the special pathogenic germs, still predisposes those drinking it to at least one disease—typhoid fever.

What, then, shall be done with the old wells? We all know that in the absence of a public supply deep tube-wells would be the best remedy. Many, very many people cannot avail themselves of this source of supply; and the next best thing is to treat these wells after a method devised by Dr. Koch, which is effective, cheap, and greatly lessens the dangers arising from the use of well-water. An iron tube, two or three inches in diameter—with its lower end perforated—is placed in the center of the well, and the surrounding space filled with fine gravel up to the highest point of water-level. This is then covered with sand to the top of the well; and a pump attached to the end of the tube makes a very effective tube-well. All water, in passing through the layers of sand and gravel, is effectually filtered, and the nitrifying organisms change the filth into harmless nitrates. A filter-bed like this removes, too, from 80 to 90 per cent. of the bacteria, and greatly, very greatly lessens the danger to which all are subjected who drink shallow well-water.

CLINICAL LECTURE.

MODERN MILITARY SURGERY; THE NEW BULLET; PORTABLE DRESSINGS; TELEPHONIC PROBE.

Clinic at the Buffalo General Hospital.

BY ROSWELL PARK, A.M., M.D.,
PROFESSOR OF SURGERY, UNIVERSITY OF BUFFALO.

I HAVE the opportunity, partly through the courtesy of Dr. Appel, now stationed at Fort Porter, of giving you a talk on gunshot-wounds, and of showing you the latest missile in use by the United States Army. The old cartridge used by the regular army, and still in use by the National Guard, contains 70 grains of powder, and the recoil is equivalent to 90 pounds. Thus, after firing a number of rounds the shoulder is likely to become black-and-blue. Then, too, the weight of a sufficient store of such cartridges is considerable. This new cartridge, designed to be used in a rifle made for the United States Government, contains a bullet of 0.30 caliber and 37 grains of powder of the smokeless variety. The projectile is conical and composed of a copper and nickel shell, into which is forced an alloy of tin and lead. The bullet is not altered in shape by its discharge from the piece, nor by its flight through the air. It has a tremendous initial velocity—over 2000 feet per second at the muzzle. The consequence is that, with a much lighter cartridge, fired from a much lighter gun, the modern soldier is about trebled in effectiveness in comparison with his comrade of ten years ago.

As to the surgical side of this matter, the penetrating power of the modern bullet is much greater than that of the old. At a distance of 1000 yards, the old bullet would go into solid oak about three inches. This will penetrate about twenty-two inches, and without altering in shape, whereas the old bullet would be shattered. The old bullet was fairly effective at 1000 or possibly 1500 yards. At a greater distance it would not usually inflict a serious wound, and it was impossible to aim accurately enough to be sure of hitting a man at any such distance. With the improved sighting of the new rifle, however, in connection with the modern projectile, a marksman can kill his man at two miles, and at 2000 yards the projectile will pass through three human bodies. The new bullet does not make so large a wound as the old one, but it does harm in a different way. If I had to be shot through the abdomen at a distance of 1000 yards, I should prefer to be hit by the new projectile, because it inflicts a smaller wound. But modern warfare is going to be more effective and more quickly fatal, because the fighting can be done at long range, as prize-fighters say. Dr. Appel tells me that the field-cannon having a caliber of three inches and firing a projectile similar to this small one is effective at a distance of eight miles.

When a bullet of the old type would pass through the head of the tibia the bone was shattered, and there was an extensive laceration, both external and internal. This modern projectile, on the other hand, will penetrate the bone, leaving a clean-cut hole, like that made by an augur. There is thus a kindly side to modern warfare. The soldier is disabled just as much as though his leg were shattered, but there is not the subsequent necessity for amputation. In other parts of the body, also, this bullet affords a chance for conservative surgery. The soldier can carry twice as much ammunition without increasing his load; he can defend himself with greater readiness; and if he is hit, unless in some mortal part, he has a better chance of surviving the wound.

Many of the soldiers of our army are now supplied with a little packet made up of silk coated with rubber, and containing sublimate-gauze, cambric, and triangular bandages, with a couple of safety-pins. On each triangular bandage are a number of pictures showing how it may be applied to almost any part of the body. In our army the hospital-stewards, company-bearers of

stretchers, and the hospital-corps carry these. In the German army every man carries such a packet. Let us suppose that a man is shot from a distance. He has been taught to double up these little compresses and to put one on each side of the wound—for it must be remembered that this projectile will usually penetrate the body, instead of remaining inside like the older missiles—and to complete the occlusive dressing by applying the triangular bandage. Directions are also printed on the oiled-silk cover. Such a packet as this is available for others than soldiers, and years ago I did my best to have them introduced among the policemen, and to have an arrangement made for elementary instruction in their use. The idea was not carried out, but perhaps, with a more liberal *régime*, it may be at some future time.

I wish to show you a new instrument that I have just procured and which bears on the topic that we have been discussing. Bullets of the modern style will not be likely to lodge unless they have gone through several files of men, but pistol-balls and bullets of the old style are not so likely to escape. The old Nélaton probe was a piece of metal with an end of unglazed porcelain melted on it so as to be perfectly secure. This was passed along the evident bullet-track, and, if it struck the lead, there would be left a black mark on the porcelain. This ingenious instrument is still effective in some cases. In a general way, modern surgeons are opposed to hunting for bullets. The harm that a bullet does is mainly at the instant of its flight, and, as a rule, it then becomes an inert foreign body, and thus it does not call for removal unless it press on some particularly sensitive tissue like that of the nervous system. There are cases, however, in which we must search for bullets and there are times when patients insist on their removal. A variety of electric appliances have been devised for locating the ball, and the thought has arisen in many minds that if we could bring something in contact with the metal which shall effect an electric contact, the current may be made to swing a needle on a dial or ring a bell or give some other warning. Those of you who are well informed in electricity may understand what is meant by the induction-balance. This was tried in the case of President Garfield, but failed because it was too delicate. There have been a number of attempts made to adapt the telephone to indicate when the point of the probe has touched the bullet. This is the latest model of Dr. Girdner's telephonic probe. Dr. Girdner is a New York surgeon, not in military practice; but usually in times of peace the civil surgeons see as many bullet-wounds as those in military practice. The slightest difference in the currents passing in the cords connected with the ear-piece of the telephone produces a faintly audible click. One of the wires is connected with an insulated probe having a metallic end. The circuit is completed by a metallic electrode placed in the patient's mouth, where the moisture insures the conduction of the current. The instant the end of the probe comes in contact with the bullet a slight grating or buzzing sound is heard. By repeating the experiment once or twice, you can assure yourself of the location of the ball. Other experimenters have completed the electric circuit by placing a sponge electrode on the surface of the body, but Dr. Girdner's method is superior. I would suggest only one improvement on the instrument in its present form, namely, the attachment of an elastic band to hold the receiver to the ear, so as to leave both of the surgeon's hands free.

CLINICAL MEMORANDA.

TWO CASES OF AKROMEGALY.

BY HERMON C. GORDINIER, A.M., M.D.,
OF TROY, N. Y.;
PROFESSOR OF PHYSIOLOGY AND LECTURER ON THE ANATOMY OF THE NERVOUS SYSTEM, ALBANY MEDICAL COLLEGE.

CASE I.—William U., aged seventy-seven years, a married Frenchman, was by occupation a shoemaker. His father and mother had died at an advanced age, the cause of death being unknown. The man had had a brother who had died of some form of paralysis at seventy-eight years of age. No nervous history exists in the family, apart from the brother's case. The patient's general health was excellent until five years ago, saving periodic attacks of headache. When quite young he had an attack of pneumonia; but he can recall to mind no other illness until the existing enfeeblement began. The present condition began about five years ago, with frontal and occipital headaches, which were frequently accompanied by dizzy spells, which often caused the patient to fall. These attacks have gradu-

FIG. 1.

ally increased in severity until the present time, and seem, apart from his general weakness, a source of great discomfort. His children have noticed, during the past year particularly, that his memory is very defective, that he is easily amused, and laughs heartily at the most silly trifle; that he seems to take no interest in things about him, and sits most of the time. At rather frequent intervals he labors under fleeting delusions. Prior to the age of sixty-eight his daughter noticed that he began to be stooped, formerly having been noted for his upright carriage. She has observed for a long time the increase in the size of hands and feet. He suffers from thirst,

and consumes large quantities of water, and has at all times an enormous appetite, and frequently will arise at night and eat heartily. He is very sensitive to cold, and has a slight cough during the winter, which disappears with the onset of warm weather. He has frequent attacks of diarrhea, but no hemorrhage from any mucous surface. He voids about three quarts of urine in the twenty-four hours. The teeth have been moderately well preserved until within three years, when a gradual decay and falling out began to take place.

The patient is short, stout, and heavy-boned. He is bent decidedly forward. His height is 5 feet 4½ inches. The hands are very large and broad, the fingers and thumbs large and sausage-shaped and misshapen. The feet also are large, broad, and flat. The chest is very large and deformed. The head is large, the forehead retreating; the superciliary ridges are large and overhanging; the hair is long and coarse, and there is no tendency toward baldness. The ears are normal in size. The skin of the face is thrown into great wrinkles, but is not specially unctuous in feel or appearance. There is no thickening of the skin, which can easily be pinched into folds. The naso-labial folds are accentuated. The nose is moderately long and very broad; the alæ nasi are bulbous; the nasal openings broad. The lips are large, everted, and thickened, but not cyanotic. The malar bones are large, bulky, and prominent. The lower jaw is massive. Prognathism is well marked. There is slight puffiness of the loose tissue about the lower lids. The tongue is long and broad, and projects about 1½ inches beyond the incisors. The thyroid is not palpable. The face is oval; the teeth in the lower jaw are fairly well preserved, but separated by distinct spaces. There is no sponginess of the gums or pallor of the mucous surfaces. The voice is coarse and rough. The following measurements were taken:

Head, occipito-frontal	24⅛ inches.
Occipital protuberances to glabella	14⅛ "
Occipital protuberances to tip of chin	11½ "
Top of forehead to tip of chin	9½ "
Top of forehead to upper end of nasal bone	3½ "
Length of nose	2⅝ "
Width of alæ nasi	1⅞ "
Septum to tip of chin	3¼ "
Between malar bones	5½ "
Width of mouth	2½ "
Thickness of lower lip	¾ inch.
Length of lower lip	⅝ "
Thickness of tongue	1¼ inches.
Projection beyond incisor teeth	1½ "
Between mastoids	15 "
Temporo-maxillary joint to symphysis	6⅜ "
Between angles of lower jaw	9½ "
Length of ears	2⅞ "
Width of ears	1¼ "

The chest is large in every diameter; the antero-posterior and lateral diameters are about the same. There is marked dorso-cervical kyphosis, with slight lower dorsal and lumbar lordosis, and slight scoliosis. The head is thrust forward, the chin almost touching the sternum. The left shoulder is lower than the right. The chest bulges posteriorly, more so on the right side. The scapulæ are massive, the right larger (7½ inches) and more prominent than the left (7⅛ inches). The clavicles are prominent (right 7⅛ inches, left 7¼ inches). The sternum bulges but slightly. The upper ribs are large and prominent. The circumference of the chest through the nipple is 39 inches; at the third rib, 38 inches; in the lower mammary region, 37 inches; on deep inspiration, 39¾ inches; on forced expiration, 38½ inches. The chest moves up and down as if one solid mass, there being but very slight expansion.

The pulmonary resonance is normal; liver-dulness begins in the fifth intercostal space in the mammillary line, in the seventh interspace in the axilla, and in the ninth interspace posteriorly. No vesiculo-tympanitic note is to be heard anywhere over the chest. Good vesicular murmur is present. Expiration is nowhere prolonged; no adventitious sounds are to be heard. Percussion-dulness is not elicited over or on either side of the manubrium. Vocal fremitus is normal. Respiration averages 26 per minute.

The area of cardiac dulness begins at the third rib and extends laterally to the anterior axillary line. The aortic second sound is accentuated. The apex-beat is situated in the sixth interspace on the left, outside the nipple. The first sound is booming, and a little murmurish. There is no epigastric pulsation. The superficial veins of the chest are not prominent, and there is no pulsation of the jugulars. The carotids and radials are atheromatous. The pulse is 72. Arcus senilis is well marked.

The arms are short and massive, the muscles well developed but flabby. The elbow-joints and the wrist-joints are broadened; the lower ends of the bones of the forearms enlarged. The distance from the acromion process to the styloid on the right side measures 23 inches; on the left, 22 inches. The hands are truly enormous, being very broad in comparison with their length; the fingers are very bulky and broad, the thumbs short and broad, the phalangeal articulations enlarged and freely movable. The hands present a purplish hue, and the veins of the dorsum of the hands are overdistended. The palms of the hands and the palmar surfaces of the fingers are covered with enormous cushion-like pads, which do not pit on prolonged pressure, and which give one the sensation of a diffuse cellulitis. Pads of a like nature are found on the palmar surface of the thumbs and about the thenar eminences.

The circumference of the wrist on the right side is 7½ inches; on the left, 7½ inches; that of the hands is 11 inches on the right; 11 inches on the left. From the styloid process to the tip of the middle finger measures 8½ inches on the right, 8 inches on the left. The circumference of the thumb is 3½ inches.

The feet are very large and broad; the veins of the dorsum are prominent, the heels project well backward, and the bottoms of the feet are flat. The well-known cushion-like pads, so aptly described by Marie, are well marked and completely surround the heels. The toes are uniformly enlarged, the big toes being much broadened, and the cushion-pads are present on the plantar surfaces of all the toes. The longest diameter of the feet is 10⅝ inches right, 10¼ inches left. The circumference over the heel and instep is 15¼ inches left foot, 14⅛ inches right. The circumference of the back of the toes is 9 inches right, 8¾ inches left; the greatest width is 4⅝ inches left, 4¼ inches right. The length

of the great toes is 4 inches; the circumference 3¾ inches right, 3½ inches left.

The patellæ are not specially enlarged; the ankle-joints are strong and massive; the lower ends of the tibiæ are enlarged.

The patient is easily amused, and laughs heartily at mere trifles. His memory is very defective. The mind is frequently occupied by fleeting delusions. At present he labors under two delusions. One is that he has been offered a very fine position and that he must immediately leave to secure it; the other is that he will be presented with a very costly and beautiful gift. Sometimes he is extremely happy, singing, whistling, etc.; and then within a few minutes he will become depressed, melancholy, and listless to an extreme degree.

The pupils react to light and in accommodation. There is no hemianopia. The Wernicke hemiopic pupillary reflex is present. Movement of the eyeballs is perfect. The optic discs are normal. Hearing is still defective. Complete anosmia is present. Sensation of taste is perverted. No other sensory disturbance exists. There is no motor paresis and no muscular tenderness. The bladder and rectum are normal. There is no change in the temperature-sense. The reflexes, superficial and deep, are normal.

The urine varies in amount from three to four quarts; its reaction is acid; the specific gravity 1020. There is present neither sugar, nor albumin, nor blood, nor casts.

Examination of the blood discloses slight leukocytosis, the excess being due mostly to neutrophiles, with a few eosinophiles; unicellular leukocytes are scarce. The red corpuscles appear normal; blood-platelets are not found, and also no nucleated red corpuscles.

The hemoglobin-estimation is 85 per cent.

The blood-count shows 4,500,000 red cells to the cubic millimeter.

On May 25, 1895, the patient complained bitterly of frontal and occipital headache, which was attended with marked vertigo. The appetite was enormous, and the man was constantly hungry. He had pains, neuralgic in nature, in the extremities. During the heated spell he sweat moderately; he ordinarily sweats but little.

On June 3, 1895, he was greatly prostrated, and very much stooped. He complained constantly of dizziness and headache, and had a severe fall from vertigo.

CASE II.—My attention was directed to this case by my student, Professor McKenna, who observed him among a crowd of inmates at the Rensselaer County Hospital, and thought from his general appearance that it was an undoubted case of akromegaly.

John W., aged sixty-three years, an Irish widower, had been at different times a tailor and a miller. His father had died of old age, his mother in childbirth. He has two brothers living and in good health. There is no history of insanity or other nervous affection in the family. The patient had typhus fever in 1849, but otherwise has been in perfect health. He does not suffer from headache or dizziness. He has no correct conception of the length of time that he has been ill or of any special changes that have taken place in his bony system, being an individual of rather inferior mental development and without education. But has noticed that he requires a much larger hat than formerly.

He complains of occasional attacks of facial neuralgia, and has had two distinct attacks of erysipelas. He has no dyspnea, no thirst, and no great hunger, but enjoys a good appetite, and does not sweat immoderately. He has been alcoholic all his life, but denies syphilis. He uses No. 9½ shoes. There is no history of goiter. The memory is good and vision is fair. The patient never suffered from asthma or dyspnea.

He has a large head, with a retreating forehead and prominent and overhanging superciliary ridges. The occipital region of the skull is very conspicuous.

FIG. 2.

The patient is short and stout, coarse-featured, and 5 feet 4 inches high. He stoops forward. The gait is slow, the feet being held widely apart, and the head carried well forward, so that the chin almost touches the sternum. The hair is coarse, sparse over the occiput, and normal in amount in other localities. There is marked cervico-dorsal kyphosis. The voice is rough and slightly hoarse.

Prognathism is well marked. The lips are thickened and everted, particularly the lower one. The naso-labial folds are greatly accentuated. The nose is short, thick, and bulbous at its extremity. The feet are large. The chest is very massive and prominent. The pulmonary expansion is slight. The clavicles, ribs, and scapulæ are very large.

The head is large, the forehead retreating, the superciliary ridges enormously developed and overhanging. The occipital region of the skull is prominent. The vertex is rounded. The lower jaw is very massive. Many teeth have fallen out, and those remaining are in a decayed and filthy condition; those of the lower jaw are irregularly set and project decidedly beyond the upper. The malar bones are large and prominent. The zygomatic arches are well developed.

The nose is prominent and very broad, especially at its root. The nasal openings are large, the extremity of the nose bulbous, and the member itself decidedly purplish. The lips are much thickened, the lower one considerably more everted than the upper and projecting beyond it. The ears are unusually large, of a waxy, greasy

appearance, and seem thickened. Transverse wrinkles exist on the forehead. There is no edema and no thickening of the skin. The skin of the face has a decidedly oily appearance and feel. The face might in general conformation be likened to that of an ape. The whole face, with the massive lower jaw and the prognathism, would remind one of a depraved criminal.

The tongue is large, thick, and broad. It can be protruded about two inches beyond the incisor teeth. The gums are pale and do not bleed on severe irritation. The patient has never had hemorrhages from mucous surfaces.

The following measurements were made:

Circumference of head	24½ inches.
Distance from forehead to occiput	13 "
Distance from occipital protuberance to tip of chin	13¾ "
Distance from top of forehead to tip of chin	9 "
Distance from top of forehead to upper part of nasal bone	3½ "
Distance from upper part of nasal bone to tip of nose	2⅞ "
Width of alæ nasi	2 "
From septum to tip of chin	3⅛ "
Width between malar bones	7 "
Width of mouth	2⅝ "
Thickness of lower lip	1 inch.
Length of lower lip	2½ inches.
From mastoid to mastoid	14 "
Lower jaw, from gums to symphysis	2 "
Length of jaw from temporo-maxillary articulation	6¾ "
From angle to angle of lower jaw	9¼ "
Length of ears	3½ "
Breadth of ears	1¾ "

The chest is enlarged in every dimension; the antero-posterior diameter is greater than the transverse. The upper border of the sternum, with the first three ribs and costal cartilages, is bulged markedly forward. The clavicles are very large, measuring from sternal end to acromion 6½ inches on the right side, 7¼ inches on the left. The ribs feel much thickened and enlarged, particularly the upper prominent ones. They are united with those below, judging from the obliteration of the intercostal spaces and from the great resistance offered. The veins on the right side of the chest are visible. None is to be seen on the left. There is slight lordosis in the lumbar region, and well-marked cervico-dorsal kyphosis. Posteriorly in the right upper dorsal region the chest bulges considerably; there is no bulging on the left side. The scapulæ are prominent and massive; their spinous processes are well defined. From the acromion process to the angle of the scapula measures on the right side 10¼ inches; on the left side 10 inches. The spine of the right scapula measures 7¾ inches, that of the left 7 inches. The right shoulder is decidedly lower than the left. There is no fulness at the back of the neck. The chest moves up and down as if one solid piece, and apparently there is no chest-expansion in an anterior or a lateral direction. The vocal fremitus has its normal disparity.

The pulmonary percussion-note is normal. Liver-dulness begins at the fifth rib; cardiac dulness at the lower border of the fourth rib; splenic dulness is normal. An area of dulness exists beneath the upper part of the sternum and extends laterally beneath the first ribs. No vesiculo-tympanitic note is to be heard anywhere over the chest. The heart-sounds are normal. The apex-beat is in its normal position. There is no prolonged expiration; the vesicular element is everywhere well marked. The pulse is 64, soft, full, and strong; respirations are 20; the vessels are not atheromatous. Measurements of the chest:

Circumference of second rib	38½ inches.
Circumference of nipple	38 "
Circumference in lower mammary region	37 "
On deep inspiration	39 "
On deep expiration	38 "

The thyroid gland is not palpable.

The abdomen is protuberant and lax, and the skin and soft parts are thrown into great transverse folds.

The hands are broad and spade-shaped; the veins of the forearm are moderately distended; the fingers are broadened; the joints are all enlarged and freely movable; the finger-ends are bulbous and cushioned on the palmar aspect; the nails are oval; the thumbs are long and broad.

The circumference of the wrist-joint on the right side is 7¾ inches; on the left side 7¼ inches.

The circumference of the hands when closed is on the right side 11 inches, on the left side 10¾ inches.

The distance from the styloid process to the tip of the middle finger is on the right 8 inches, on the left 8 inches.

The muscles are soft and flabby.

The feet are long, broad, and flat; all of the toes, save the big toes, are arched at the junction of the first and second phalangeal joints. The large toes are broad.

There is no enlargement of the lower ends of the right tibia and fibula. On the left is an old fracture, with deformity and marked thickening of the whole shaft of the tibia.

A marked pad or cushion of flesh is present about the inferior, lateral, and inferior surface of heels, which project posteriorly beyond the os calcis.

The longest diameter of the foot is 10⅛ inches on the right, 10½ inches on the right; about the heel and instep, 13 inches. The circumference of the ball of the toes is 8½ inches on right and left; the greatest width is 4 inches on the right, 3⅞ inches on the left. The length of the great toe is 3¼ inches on both sides. The circumference of the big toe is on the right side 3½ inches, and on the left 3 inches. The patient is flat-footed; the gait is clumsy and waddling, the legs being spread wide apart.

The pupils are moderately contracted, but respond to light and in accommodation. The movements of the eyeballs are perfect. There is no evidence of sympathetic irritation or paralysis. Wernicke's hemiopic pupillary reflex is present; there is no hemianopia. The hearing-distance is reduced to 3 inches on the left side, to 4 inches on the right, in consequence of a chronic catarrh of the drum. The other cranial nerves are intact.

There is no muscular tenderness and no anesthesia. The reflexes are normal, and there is no paresis. Apart from the low order of intelligence there exist no mental symptoms. The urine is normal in amount, and contains no albumin, sugar, blood, or casts.

There exists a normal proportion between the red and white blood-corpuscles. The whites are mostly neutrophiles, with an absence of eosinophiles. There are no nucleated red corpuscles. The hemoglobin is estimated at 70 per cent. The red corpuscles number 4,800,000 to the cubic millimeter. The blood flowed freely and was very cyanotic.

EXOPHTHALMOS (GRAVES' DISEASE) WITHOUT THYROID ENLARGEMENT.

BY P. S. DONNELLAN, M.D.,
OF PHILADELPHIA,
VISITING PHYSICIAN TO ST. MARY'S HOSPITAL; LECTURER ON PHYSICAL DIAGNOSIS, MEDICO-CHIRURGICAL COLLEGE.

M. H., a married woman, aged forty years, a weaver by occupation, was admitted to my care at St. Mary's Hospital on May 4, 1895. She presented the following history, for which I am indebted to Dr. Joseph H. Ross, one of the resident physicians at the hospital.

Her father had died at the age of forty-five years from chronic nephritis; her mother at the age of thirty-two years of puerperal fever. All of her brothers and sisters had died in infancy. In the families of the parents there was no history of nervous disease or of any disease similar to that from which the patient was suffering.

The patient herself was born in Scotland, and came to this country when fourteen years of age. She had always enjoyed good health until twelve years ago, when she was treated at this hospital for typhoid fever, from which she recovered without complication or sequel. She remained in good health until three years ago, when her present illness began—the result, she states, of a fright from a beating she received from her husband. There was no history of rheumatism or of alcohol, and specific infection was denied.

Since her present illness began, the woman complains of constant and severe cardiac palpitation, with shortness of breath, vertigo, and insomnia. For three months previous to admission there has been swelling of the feet, particularly after standing or walking for any length of time; and the quantity of urine was much diminished. The patient has also noticed that her eyeballs have become very prominent, and they feel, as she expresses it, as if they would bulge out of her head. She suffers from occasional attacks of bilious vomiting; her appetite is poor; her bowels are constipated, and her tongue is coated.

The patient is a feebly nourished anemic-looking woman. Her eyeballs are very prominent. In looking downward the upper eyelids do not follow the descent of the eyeballs (von Graefe's symptom), and, while the voluntary movements of the lids are unimpared, the complete absence of involuntary winking (Stellwag's symptom) is noted. Dr. Louis F. Love, ophthalmologist to the hospital, kindly made an examination of the eyes for me and confirmed these observations. He reported in addition: "Pupils, 2½ mm., about equal; active to light, but sluggish in accommodation and convergence. Ophthalmoscopic examination—cornea maculated, rest of media apparently clear; discs oval, axis 180°; veins well filled, with dilatation; marked astigmatism in each eye." Dr. G. Hudson Makuen, laryngologist to the hospital, kindly examined the patient for me, and reported that there was no enlargement of the thyroid gland.

There was visible pulsation in each carotid artery noticeable at a distance of six feet from the patient. The pulse varied between 160 and 190 beats per minute, except when the patient had been taking two ounces of infusion of digitalis in the twenty-four hours for several days, when it dropped to 68 beats per minute, only to rise again when the digitalis was suspended. The vascular tension was much below normal.

In examining the chest, increased frequency of respiration (from twenty-five to thirty per minute) was noticed, but otherwise the respiratory functions were normal. The heart was hypertrophied, as shown by increased area of cardiac dulness downward and to the left. The impulse was felt in the sixth interspace to the left of the nipple-line. Auscultation revealed violent and irregular cardiac action, with increased frequency of the number of beats and synchronous with the radial pulse. A well-marked mitral systolic murmur was heard at the apex, transmitted to the axilla and to the angle of the scapula. The urine was negative chemically and microscopically, and upon admission measured only two ounces in the twenty-four hours, but rest in bed, and the use of the infusion of digitalis with strychnin, rapidly brought the quantity up to the normal.

The principal points of clinical interest in this case are the absence of enlargement of the thyroid gland and the visible pulsation in the carotid arteries. Most observers with whose studies I am acquainted regard these phenomena as unusual. Trousseau called cases of this kind *formes frustes* (abortive forms), and considered them important types of the disease. An elaborate study of cases in which either the goiter or the exophthalmos may be wanting was made by Marie, who found that in such cases tachycardia was frequently present, and often accompanied by tremor. Hirt quotes the observations made in his wards by Ernst Cramer, who was able to confirm the results of Marie. The consensus of opinion seems to be that the excited and accelerated heart-action is the first characteristic symptom of Graves' disease; then follows symmetric enlargement of the thyroid gland, the exophthalmos being, as a rule, of later development. Whether in this case the natural order of things has been reversed, and the enlargement of the thyroid gland may yet take place, only subsequent observation can determine.

SUCCESSFUL LIGATION OF THE LEFT COMMON CAROTID ARTERY.

By FRANK L. LAPSLEY, A.B., M.D.,
RESIDENT INTERNE, LOUISVILLE CITY HOSPITAL.

On March 27th I was called to see M. E., aged thirty-three years, a bricklayer, and found him in a state of intoxication, with the surroundings strongly suggestive of his having attempted suicide. I learned that in attempting to shoot himself through the head his arm had been struck by someone, knocking the pistol downward, when it was discharged. The bullet, of 32-caliber, entered the mouth and passed out at the left angle, just between the superior and inferior maxillary bones. There was evidence of slight hemorrhage having occurred, but this had ceased when I reached the man. He was at once conveyed in the ambulance to the city hospital, where, with strict aseptic precautions, an exploration of the wound was made, using my little finger as a probe. I found the course made by the bullet to be slightly upward and outward. The bullet was located against the ramus of the inferior maxillary bone and was extracted with a pair of artery-forceps. It was so battered out of shape I could not determine positively, but supposed that it was removed *in toto*.

Further examination showed that the bullet had struck the ramus near its lower anterior border. Three small spicules of bone were felt and removed.

Slight hemorrhage followed this manipulation, but was easily controlled by packing with iodoform-gauze. The wound was thoroughly irrigated with a solution of mercuric chlorid 1 : 3000.

At the end of forty-eight hours there was evidence of beginning suppuration, which continued freely, despite the daily irrigation with mercuric chlorid and packing with fresh gauze. The jaw and neck were so swollen as to prevent the man from opening his mouth further than to admit a small glass-tube, through which he took stimulants and nourishment. The administration of morphin and applications of heat were necessary to relieve the intense suffering.

At midnight of April 10th, two weeks from the reception of the injury, the man suddenly had a profuse secondary hemorrhage. This was readily controlled by packing firmly in the angle of the mouth. This hemorrhage was, I think, due to the process of suppuration extending into the walls of one of the facial branches. On the next day I deemed it advisable to establish freer drainage, and accordingly made a counter-incision in the neck on the left side about two inches from the median line. This opening communicated with the mouth, and the entire tract was irrigated daily with mercuric-chlorid and hydrogen-dioxid solutions. The patient continued to suffer great pain in the jaw, the side of the face, and the ear. The swelling and inflammation of the neck and the side of the face subsided.

On April 17th, just one week later and at the same hour of night, the man had another and more profuse hemorrhage than the first. I reached his bedside quickly and observed blood to be streaming from the wounds both in the mouth and neck. I at once compressed the carotid artery and the hemorrhage ceased, but the patient having lost two pints of blood was so exsanguinated that he fainted. He was resuscitated by stimulants and application of heat.

I packed the wound in the mouth and applied a tight compress over the wound I had made in the neck. I realized that the case now demanded immediate surgical interference; so I summoned Drs. Grant, Dugan, and Vance, and when they saw the case a few hours later a false aneurism existed.

It was agreed best and safest to ligate the common carotid artery, and the operation was undertaken by Dr. Grant and myself. The patient was accordingly prepared and anesthetized, taking the anesthetic badly. The point selected as the most favorable was that part of the vessel which is at the level of the cricoid cartilage. It is unnecessary to give a detailed account of the steps of the operation, but suffice it to say the vessel was reached with little difficulty and ligated with No. 10 braided Chinese silk, bearing in mind the relation thereto of other important structures. The incision was carried up over the angle of the jaw, where, after turning out some clots, considerable necrosis of the bone was discovered. Another portion of the bullet was found lying against the anterior surface of the bone, showing that it had split and perforated the ramus. This was thoroughly scraped and irrigated, and allowed to remain open and granulate from the bottom. Two sutures were introduced at the lower angle of the wound and the usual antiseptic dressings applied. The man rallied from the shock nicely, and was at once put upon stimulants, reconstructives, and plenty of nourishing diet. His convalescence was gradual and permanent. The wound healed kindly, and he now suffers no inconvenience, except a slight stiffness of the jaws, which I think he will eventually overcome.

The pulsation in the temporal artery is entirely absent on the left side. The patient was discharged from the hospital on June 24th.

COMPLETE PROLAPSE OF A PREGNANT UTERUS. OPERATION, FOLLOWED BY ABORTION.

By J. MASON HUNDLEY, M.D.,
OF BALTIMORE, MD.;
ASSOCIATE PROFESSOR OF DISEASES OF WOMEN AND CHILDREN IN THE UNIVERSITY OF MARYLAND.

The case herewith reported demonstrates the value of amputation of the cervix with repair of the perineum for the cure of complete prolapse. Various pessaries, together with tampons and attention to the general health, had all been tried without effecting a cure. Mrs. H. E. H., aged twenty-three years, the mother of one child, four years of age, presented herself at the University of Maryland Clinic, July, 1893, with the following history: Since the birth of her child she had suffered with bearing-down and dragging pains in the lower abdomen, especially when on her feet for any length of time. For the past six months she had been unable to lead an active life because her uterus came down so low, causing pain and unendurable discomfort. She was separated from her husband and had to make a living for herself and child, and, therefore, sought relief.

Upon examination, the uterus was found entirely without the vulva. The cervix was eroded, and the mucous membrane of the vagina presented the appearance of

parchment. There was no disease of the adnexa and no mass within the pelvis; nor were there fibroids of the uterus. The perineum was not lacerated, but greatly relaxed, and the muscles attenuated. The woman was extremely emaciated. She menstruated regularly and not profusely, and she said that she had just gotten over her sickness. We admitted her at once to the gynecologic ward, and she was operated on by me, as Dr. William T. Howard was absent from the city. Just before operating, a probe was passed into the uterus, to demonstrate to the class the great difference between the length of the uterus in the third degree of prolapse and that of the same organ in its normal position. The cervix was amputated at its vaginal attachment and the raw surface covered over by mucous membrane. The modified Emmet operation was performed on the perineum. On the evening of the day of the operation I was telephoned for, and on reaching the hospital found the woman bleeding quite freely. I examined her as best as I could and found that the blood was coming from the uterine cavity. I tamponed the vagina, and on removing the dressings in the morning I found in the vagina from a four to a six weeks' fetus. The woman made an uninterrupted recovery in spite of the abortion. After leaving the hospital she went to live with her husband again, and last September gave birth to a full-term child, the labor being normal and not unusually tardy.

I am sure this woman intentionally deceived me as to her menstruation. The experience, however, taught me a useful lesson, which will not be easily forgotten. Whatever the condition of a uterus, the possibility of pregnancy should never be lost sight of. I have had no experience with Hegar's sign of early pregnancy in a procidented pregnant uterus, but, under normal conditions, I believe it a most valuable sign; in fact, I have never found any condition of the uterus giving the same thinning of the lower uterine segment as that found in pregnancy. If I had looked for the sign in this case, I might have demonstrated it, and have avoided the blunder of operating upon and introducing a probe into a pregnant uterus.

BACTERIOLOGIC NOTE.

A NEW METHOD OF STAINING FLAGELLA.

BY ROBERT L. PITFIELD, M.D.,
OF PHILADELPHIA

LOEFFLER'S method of staining flagella is probably the one most commonly and generally employed. This consists in treating the bacteria to be stained with a mordant made up of tannic acid and ferrous sulphate, and then staining the bacteria with a solution of an anilin color in water.

I have devised a method which is simple, and, in my hands, much more reliable and easier of execution. It is as simple as the staining of bacteria with ordinary carbol-fuchsin, and I have stained over fifty preparations of flagellated micro-organisms, each time demonstrating the flagella most satisfactorily.

The method consists in the use of but a single solution, which is at once mordant and stain. The solution should be made in two parts, which are filtered and mixed.

A.

Saturated aqueous solution of alum	10 c.cm.
Saturated alcoholic solution of gentian-violet	1 c.cm.

B.

Tannic acid	1 gm.
Distilled water	10 c.cm.

The solutions should be made with cold water, and immediately after mixing the stain is ready for use.

The cover-slip is to be carefully cleaned, the grease being burned off in a flame, and after it has cooled the bacteria are spread upon it, well diluted in water, care being taken to exclude culture-medium. After the preparation has been thoroughly dried in the air it should be held over the flame with the fingers, as Loeffler has directed. Afterward the stain is gradually poured on the slip and heated gently, bringing the fluid almost to a boil; the slip covered with the hot stain should then be laid aside for one minute, then washed in water and mounted.

Upon examination, the bacteria, both isolated and in clumps, will, if motile, be found to have the flagella clearly and delicately defined. In the middle of the cover-slip, as well as around the edges, the bacteria will be found equally well stained; the clumps being surrounded by a zone of delicate fringing flagella, each being well stained and distinctly outlined from its fellows.

If a clean preparation is desired, the stain, after mixing, may be filtered, but I have found that the most reliable method is to use the unfiltered stain. In the case of the former a clear field is produced without the detritus, etc., precipitated on the glass around the micro-organisms; and all the flagella are stained, but not so distinctly as with the unfiltered solution.

If the filtered stain is used, a second stain of anilin-water containing gentian-violet had better be used, which should be applied but a moment and then washed off, thus leaving a clean field, showing only the bacteria lightly stained, with their flagella still more lightly colored.

In examining the different bacteria, I have found that the bacillus of typhoid fever, the colon-bacillus, the cholera-bacillus, and the bacillus of hog-cholera, each stained well by this method, and without the addition of any acid or alkali to the mordant, such as Loeffler uses.

The bacillus of typhoid fever showed the flagella most beautifully, and there seemed one flagellum to each cell that stained more deeply than the others and appeared larger and stronger.

As to the keeping qualities of the stain I have not fully ascertained, but presumably it should be mixed daily to yield the best results.

MEDICAL PROGRESS.

Hepatic Abscess following Duodenal Ulceration Caused by a Burn.—HEHIR (*Indian Medical Record*, vol. viii, No. 12, p. 438) has reported the case of a soldier who sustained a severe and extensive burn, principally involving the face, scalp, front of the neck, and the trunk, due to the explosion of a kerosene-oil lamp. When seen, twenty minutes after the accident, the patient was in a semi-collapsed state. Morphin and atropin were at once in-

jected hypodermically, and the burned surface covered with carron-oil. On the ninth day the patient complained of pain in the epigastric region, which gradually extended until it occupied the whole of the anterior part of the abdomen above the umbilicus. The pain was increased by pressure, especially in the epigastrium, and also by cough, deep breathing, and the lateral decubitus. There was slight fulness of the liver, but no pain on pressure. On the twelfth day diarrhea began, the stools at first being semi-liquid, and later containing blood and mucus. On the twenty-first day copious hemorrhage took place, which was checked by the use of cold externally, and ergot and turpentine internally. The patient now appeared to convalesce, and on the thirty-fifth day returned to duty and continued at work for eighteen days. He was then seized with a croupous pneumonia, which ran an ordinary course, but after the crisis he failed to convalesce satisfactorily. The cough continued, with diffuse pain over the whole of the base of the right lung, and there was perceptible bulging below the lower angle of the right scapula. After this condition had continued for a month, six ounces of inflammatory fluid were on exploratory puncture removed from the pleural cavity, but without affording relief. The temperature remained elevated, and profuse sweats occurred at night. To these symptoms rigors became added, and there appeared severe pain over the liver and lower border of the chest-walls posteriorly.

After a time the liver began to increase considerably in size, the cough became more severe, dyspnea set in, and severe vomiting occurred during each exacerbation of temperature. It was believed that an accumulation of pus had formed in the liver, but exploratory puncture failed to demonstrate its presence. Some time later an exploratory operation was undertaken and fifty-nine ounces of pus were removed. The patient did well for a time, but the symptoms returning, forty ounces of pus were removed at a later date. The patient, however, failed to rally, and gradually became worse, and finally died, although twenty-seven ounces of seropurulent fluid were removed from the right pleural cavity.

Upon post-mortem examination practically the whole of the lower half of the duodenum was found in a state of patchy congestion, with five healed and two healing ulcers, the largest about the size of a shilling, the smallest a half-inch in diameter. In one place three ulcers had run into one another, and the previous ulcers were represented by a grayish depression with an uneven base, but well-defined borders. The whole of the pyloric extremity of the stomach was thickened, soft, and congested, and just above the upper semi-circumference was a rough, uneven surface with hard edges. The peritoneum over the whole of the liver was much thickened, as were also the folds of the lesser omentum, which were covered with thick layers of puriform lymph. The spleen was enlarged to three times its normal size, and its peritoneal coat was thickened and covered with lymph. The peritoneal cavity contained eleven ounces of opalescent sticky fluid, with small flakes of inflammatory material. The right lung was collapsed to one-third its normal size, and covered over its whole surface with a layer of puriform lymph. The whole of the lung was congested, and the lowest lobe and greater part of the middle lobe presented an appearance of purulent infiltration. The liver was considerably enlarged and adherent to the diaphragm throughout its upper and posterior surfaces. At one point the diaphragm was partially eroded by advancing suppuration. The right lobe was occupied by three abscesses; the largest one, the one aspirated, was full of pus similar to that aspirated, and was about the size of an eight months' fetal head; another, anterior to and below this, was about the size of a lawn-tennis ball; and the third, internal to the smaller one, was about the size of an almond. The left lobe also contained three abscesses in close juxtaposition to one another, the largest being about the size of a walnut. Surrounding each of these abscesses were a large number of small white patches, which were in reality points of suppuration, about to coalesce with the larger ones. The pus contained neither staphylococci, nor streptococci, nor amœba coli, but there were large numbers of ordinary small micrococci, and a number of small bacilli with rounded ends, which stained by Gram's method, and which presented a beaded appearance.

Multiple Diabetic Neuritis.—At a recent meeting of the Edinburgh Medico-Chirurgical Society, FRASER and BRUCE (*British Medical Journal*, No. 1795, p. 1149) reported the case of a man, thirty-six years old, coming under observation with symptoms of diabetes. There was no anemia, although there were tuberculous changes in the upper lobes of both lungs. The daily amount of urine was 194 ounces with 7187 grains of glucose, and the specific gravity was 1038. After resting in bed for a few days the quantity fell to 132.5 ounces, with 738 grains of urea and 3862 grains of glucose, and on a restricted diet to 120 ounces, with 657 grains of urea and 2736 grains of glucose. Later, pains in the ankles and legs appeared, but without numbness. Thermal and electric sensations were normal. The knee-jerk was absent on both sides. Station was steady. There was central scotoma on the right side. Despite increase in weight, no real progress was made, and finally the patient was unable to leave his bed. Dyspnea, orthropnea, and death soon followed. Upon post-mortem examination tuberculous changes were found in the upper part of each lung. There was a marked area of degeneration in one of the optic nerves. The medullary sheath was quite gone and there was parenchymatous degeneration, although the axis-cylinder was still mostly present. Between the muscular columns of the gastrocnemii there were little patches, consisting of rows of black dots, such as are seen in the muscles of the heart in fatty degeneration. These rows of dots appeared to be in the substances of the fibers, binding these together. The striation was still present.

Malposition of the Sigmoid Flexure in the Right Iliac Fossa.—MUNDELL (*Dominion Medical Monthly*, vol. v, No. 5, p. 39), in demonstrating the operation for appendicitis upon the dead subject, found the usual seat of the cecum occupied by the sigmoid flexure, which, passing transversely across the fourth lumbar vertebra, formed a bend in the right iliac fossa, and then ran down into the pelvis on the right side. On tracing the parts upward the cecum was found lying above the bend of the sigmoid, and on a level with the upper border of the fourth lumbar vertebra, the appendix lying about one inch

higher up and opposite the middle of the third lumbar vertebra. The sigmoid mesocolon blended with the right extremity of the vertebral attachment of the mesentery, and a ridge of the peritoneum ran from the outer side of the sigmoid bend along the cecum above, so that on introducing a finger into the original incision the sigmoid and the cecum above it appeared to be a continuous piece of bowel. The cecum and the ascending colon were together only three-and-a-half inches in length. The appendix was found lying coiled up on the left posterior aspect of the cecum, in one of the retrocecal fossæ, there being two. In such a case as this there might be considerable trouble in diagnosis in case of disease of the appendix, and likewise of the sigmoid flexure. Reference is made to a second case in which the sigmoid encircled the left iliac fossa, lying close behind Poupart's ligament, then running back along the margin of the pelvis across the sacrum to the right side, and then down into the pelvis.

Abortive Akromegaly with Macroglossia.—At a recent meeting of the Société Médicale des Hôpitaux, CHAUFFARD (*Le Mercredi Médical*, 1895, No. 29, p. 345) reported the case of a house-painter, thirty-two years old, who came under observation on account of difficulty in breathing, and who presented a striking enlargement of the tongue. The organ was 7 centimeters long and 21 millimeters thick, and extended beyond the lower lip 5½ centimeters. Neither the lips nor the isthmus of the pharynx was hypertrophied. For two years it had been noticed that the inferior maxilla was increasing in size. The teeth of the upper jaw had mostly fallen out and those of the lower were in advance of the line of the upper. The frontal bone was low and presented marked transverse ridges. The nose had increased in thickness in several months. The cranium was dolichocephalic, without hypertrophy of its sutures or of the frontal sinus. There was slight cervico-dorsal kyphosis, with compensatory lumbar lordosis. The penis had become thicker and longer. The thyroid gland was small and there was no evidence of persistence of the thymus. Vision was lost in the left eye. The pupillary reactions were feeble. Upon the right there was myopia, with recent slight posterior staphyloma. The papilla was hyperemic and the retinal pigment atrophic. Upon the left there was deficiency of color of the external segment of the papilla. There were, besides, headache and increased frequency of micturition. The extremities presented no change. The case is believed to be an undeveloped one of akromegaly.

Experimental Ulcerative Endocarditis.—At a recent meeting of the Berlin Society for Internal Medicine MICHAELIS (*Deutsche medicinische Wochenschrift*, 1895, No. 31, Supplement No. 19, p. 131) reported that in the course of certain experimental observations upon immunity to pneumococcus-infection, made in conjunction with G. Klemperer, ulcerative endocarditis developed in one of the animals (a dog) employed. The animal had for four months been treated with increasing doses of an intensely virulent culture of pneumococci. It appeared extremely ill five days after the last intraperitoneal injection, and death followed a day later. Upon post-mortem examination marked ulcerative endocarditis was found, perfectly comparable to that observed in man, and bacteriologic examination disclosed in the valves involved pneumococci in considerable numbers, and similar organisms were cultivated from blood removed from the heart under suitable aseptic precautions.

THERAPEUTIC NOTES.

In the Treatment of Chronic Bronchitis DUBOURG (*Journal de Médecine et de Chirurgie*, August, 1895, p. 591) has employed a combination of guaiacol and iodoform by hypodermic injection:

Take—Guaiacol	. . . .	2.5 grms.
Iodoform	. . . .	0.5 grm.
Sterilized olive-oil	. .	50 grms.

The iodoform is first dissolved in ether, a portion of which is allowed to evaporate and the residue is added to the guaiacol and the oil. Iodoform thus treated dissolves perfectly and the result is a clear and limpid liquid. Each cubic centimeter contains one centigram of iodoform and five centigrams of guaiacol. Two cubic centimeters are injected on the first days, and from three to three-and-a-half on the following days. Under the influence of this treatment expectoration is at first increased but subsequently diminished; other symptoms, cough, dyspnea, loss of appetite, etc., gradually subside.

In the Treatment of Favus the hair of the affected part is cut as short as possible and the following ointment applied upon linen:

R.—Floris sulphuris	. . .	15 grms.
Sodii carbonatis	. . .	4 "
Picis liquidi	. . . .	50 "
Tincturæ iodi	. . . .	50 "
Axungiæ porci	. . .	100 "

After the lapse of twenty-four hours the affected parts are cleansed with warm soap-water and application of the ointment renewed. The treatment is intermitted as soon as the skin desquamates freely, when resort is had to a salicylated zinc-ointment. A cure may be expected in the course of three weeks.—*Rev. de Thérapie*, No. 13; *Corresp.-bl. f. Schw. Aerzte*, 1895, No. 15, p. 480.

The Treatment of Diabetes Mellitus with Uranium Nitrate.—At the recent meeting of the British Medical Association, WEST (*Medical Press and Circular*, No. 2936, p. 153) reported the employment of uranium nitrate in doses of from 5 to 15 grains three times a day, in the treatment of a number of cases of diabetes, with the result of reducing the quantity of urine excreted and diminishing the proportion of sugar to a very small amount. It was repeatedly shown that these results followed the administration of the drug, with a return to the previous conditions upon the withdrawal of the drug. The larger doses yielded the best results.

For Summer Diarrhea.—Take

Phenyl salicylate	. .	1 dram.
Bismuth salicylate	.	3 drams.
Oil of gaultheria	. .	12 minims.
Chalk-mixture	. .	3 fluidounces.—M.

Dose: Two fluidounces every two hours. Opium may be added if there is much pain. GRIFFITH—*Phila. Polyclinic*, vol. iv, No. 34.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including postage in U. S. and Canada.

SATURDAY, SEPTEMBER 7, 1895.

THE TREATMENT OF MALARIAL HEMATURIA.

ONE of the most interesting, and, to those who have to deal with it in practice, one of the most important therapeutic problems, is the treatment of malarial hematuria. This has been discussed in all parts of the world, and nowhere has a satisfactory conclusion been reached. How the case stands in this country can be learned from a recent report, in which it is shown that one-hundred-and-seven physicians in the Southern States use thirty-two remedies in the treatment of the disease. How many theories of the disease and its cure are entertained by the contributors to the report cited does not appear, but it is safe to say that the number does not fall far short of the number of drugs. The most recent contributions to the subject come from the West Coast of Africa *via* Germany. As usual, they are diametrically opposed on a fundamental point.

Plehn[1] contends that in the hematuria of the West Coast quinin is not only useless, but that it actually causes the hematuria—a statement that has been made in other times and places. On the other hand, Küchel[1] maintains that quinin is a specific, but only when given in large doses. He quotes Steudel, who gave doses of from 8 to 12 grams (2–3 drams) of quinin in a day, repeating the dose (1 gram=15 grains) in case vomiting occurred soon after it was taken. It is not surprising to learn that Steudel had 1 case of amaurosis out of 9 cases so treated, blindness occurring on the third day, after 18 grams (270 grains) had been taken. Küchel himself had 1 case of quinin-blindness out of 4 cases treated, in the person of a small anemic woman, who took 8 grams (2 drams) in two days. To offset the statement of Plehn, that quinin causes hemoglobinuria and hematuria, Küchel mentions a patient of Steudel who took one hundred-and-twenty-three grams (nearly 4 ounces) of quinin in twenty-three days, an average daily dose of 5½ grams (82 grains), and during this time the hemoglobin of the blood rose from 16 to 64 per cent., the red corpuscles from 1,600,000 to 4,458,000 per cubic millimeter.

The first thought that strikes one in reading these articles is the singular lack of judgment of the writers, lack of judgment in practice as well as in drawing conclusions. Plehn gave doses of 1 or 1½ grams (15–22 grains) of quinin a day by the mouth, dry, or rarely 2 grams (30 grains) per rectum. Even if complete absorption took place, the doses were comparatively small; but, as a matter of fact, from the nausea and the "intractable vomiting" noted in the report, even these small doses were of little more benefit to the patient than if they had been in the doctor's chest. If Steudel's patients absorbed more quinin than those of Plehn, it was only because they were loaded with the drug. That they would absorb it was impossible of prediction. If absorption was good, amaurosis was only too likely to follow. That one patient improved under the highly poisonous dose of 123 grams (nearly 4 ounces) in twenty-three days, only proves that the absorption in that case was relatively poor or absent. Evidently Plehn's patients were more likely to escape under such treatment than were those of Steudel. Plehn does not say why he used such uncertain methods of administration, but Steudel admits that he avoided the hypodermic method because he feared abscesses and tetanus! Küchel had this same fear, though in one case he gave 1 gram (15 grains) hypodermically. Küchel gives an ingenious explanation of the results obtained by

[1] Plehn: Berliner klinische Wochenschrift, 1895, Nos. 25, 26, and 27.

[1] Küchel: Loc. cit., No. 28.

Plehn and by so many others, in which the administration of quinin seemed to provoke a fresh paroxysm of fever. He suggests that in such cases the amount of quinin absorbed is too small to check the development of the parasites, but rather acts on them as an irritant, increasing their activity, and so causing the results observed. This explanation is worthy of experimental proof.

In speaking first of the therapeutics of the writers quoted we have passed over the important matter of diagnosis. It is a curious fact that they, like many others, speak of the diagnosis of malarial hematuria as being very simple, although they also show that it is often difficult, and even if the ordinary clinical diagnosis does seem clear, it is necessary in these days to confirm it by the demonstration of the parasites. This is imperative when questions of treatment are under consideration. Not only must the presence of the hematozoa be proved, but the form or variety and the relative numbers of the parasites must be mentioned, in order to convey an idea of the indications for or the difficulties of treatment. It is true that Plehn found parasites in the blood in his cases, but his description of the organisms is insufficient. One point comes out clearly, that whereas the parasites he describes closely resembled those found in severe cases in Rome, the treatment carried out was of a kind recognized as inefficient by Italian physicians. Plehn says that the parasites of the Cameroons are not affected by quinin; but, as it is doubtful whether he ever brought them in contact with quinin, the statement is not pertinent.

It is not our intention to speak here of the treatment of malarial hematuria or hemoglobinuria in detail, but rather to emphasize certain points concerning what may be called the specific treatment. In cases such as the German-African physicians describe, and which are similar to cases occurring in various parts of the United States, there is a rapid destruction of red blood-corpuscles by the pathogenic parasite. The loss of blood from this cause is infinitely greater than that from the kidneys. In actual cases the daily loss of red blood-corpuscles in the vessels has been found equal to the direct abstraction of two-and-a-half pints of blood.

Besides the destruction of blood, the parasites produce other dangerous effects, largely toxic in character—effects which, so far as we know, are best treated by removing the cause. In order to do this quinin must be so given as to enter the circulation, and the best way of effecting this is the hypodermic method or the intravenous method as improved by Baccelli. The quinin must be given in sufficient doses, not less than 1 gram (15 grains) being taken within a short time. Doses up to 3 grams (45 grains) in a day may be used, but it is doubtful whether larger doses are proportionately beneficial, while they are certainly more dangerous. The remedy is more efficient if given at such a time as to act on the parasites in their earliest stage of development, a point that can be most accurately determined by microscopic examinations of the blood, and only in this way in those cases in which the course of the disease is irregular. The quinin, even in the doses mentioned, may exert injurious effects on the kidneys. This is unfortunate, yet it is not unique in therapeutics. No surgeon, for example, hesitates to operate when operation promises to save life, merely because he fears the effects of the anesthetic on the kidneys; yet the conditions in pernicious malaria are not dissimilar.

The fact that the malarial disease often undergoes spontaneous recovery does not essentially alter the problem, because such recovery does not always take place, nor can it be predicted in any given case. Moreover, the dangerous effects of quinin feared in these cases have never yet received scientific demonstration, all the results attributed to the drug having been observed in cases treated without quinin. After the specific action of the quinin has been exerted, as determined by the condition of the blood, the drug should be stopped. In practice this will usually be in three or four days, yet it may be earlier. The remedy is not needed at this time for its effect on the parasites; its tonic effect may be spared; and even in small doses it may have an injurious effect on the kidneys without any corresponding benefit. During this time, as well as earlier, symptomatic treatment is often indicated, and in this a number of drugs, as well as other measures, may be necessary. At the same time thermometric observations and examinations of the blood must be carried on, in order to give the earliest warning of a possible revival of the parasite—to be again followed by the administration of the specific.

We do not mean to say that such time-consuming methods as have been named are to be generally used. It would be well if they could, as they would give to medical therapeutics some of that pains-

taking accuracy which has done so much to elevate surgery to the high plane it now occupies. Yet, in order to show the value or the want of value of any form of treatment, the procedures mentioned must be followed; otherwise the same contradictions and the same errors as those that we have just criticised will recur indefinitely.

REPORT OF THE PENNSYLVANIA STATE COLLEGE FOR THE YEAR 1895.

IN this pamphlet-volume of 376 pages, containing a large amount of matter interesting only to agriculturists, and representing much careful and intelligent investigation, we note as of special medical interest an article of over thirty pages, contributed by Dr. Leonard Pearson, on tuberculosis in cattle. This presents a comprehensive summary of the extent of disease in the State College herd, and is especially valuable in view of the care that has been taken to ascertain the dangers and fallacies of the tuberculin-test.

After a brief review of the general morphology and biology of the *Bacillus tuberculosis*, Dr. Pearson points out that all domestic animals are subject to the disease, but with different degrees of susceptibility, neat cattle being most susceptible, dogs and cats the least. In passing we may note a thought as to how far this high insusceptibility to tuberculosis among the animals that are most closely associated with the household has been developed under the principle of natural selection, which has thinned out those forms that were not very resisting. Whatever may be the reason, it is fortunate that the animals which are so frequently brought into close contact with young children, sharing their playing as well as their sleeping hours, should be unlikely to suffer from so dangerous a disease.

Concerning the conditions that render dairy-cattle liable to tuberculosis, Dr. Pearson distinguishes heredity, though of course not in the sense in which that word was formerly understood, as a direct inheritance of the disease, but merely as giving weakened vital function; peculiar conformations, of which the most important is that in which the animal has a shallow and usually flat chest, with long legs; irregularities in feeding, especially overfeeding; crowded and unventilated stabling; and lack of exercise.

Cleanliness is, of course, an item in the hygiene of cattle, and we are glad to see that the excessive production of milk is indicated as a source of danger. In these days, when the demands of the public, and, unfortunately, the theoretic views of some sanitary chemists, incline toward requiring very high grades of milk, the tendency is to manage cattle so as to secure these somewhat artificial results, and produce a milk of which it might be said, if the subject were not rather too momentous for levity, that it is rich but not respectable. Under the pretence of elevating the standard of dairy-cattle, more than one sanitary official has endeavored to secure by law such limitations in the composition of milk as will certainly tend to develop artificial conditions and liability to disease. Too much publicity cannot be given to Dr. Pearson's language: "The aim should not be to discover how much it is possible for a cow to produce, but to discover how much she can produce with a reasonable amount of exertion, and without detriment to her constitution." On the other hand, it is pointed out that a return to the conditions closely approximating the wild state will be too severe a change for a race that has been through many centuries subjected to artificial conditions.

After discussing concisely, but in sufficient detail, the conditions of infection, and the general symptoms of tuberculosis, Dr. Pearson explains fully the tuberculin-test as applied by him in this State. He employed the preparation made by Koch, as well as that made by the Bureau of Animal Industry in Washington, and by the Agricultural Experiment-Station at Newark, Delaware. No important difference was noted in the efficiency of these samples, but it is pointed out that no tuberculin should be used unless prepared by those known to be competent. "For purposes of injection the tuberculin is diluted with a 1 per cent. solution of carbolic acid in freshly boiled distilled water to a strength of 10 per cent. . . . The exact amount to be injected must depend somewhat upon the size of the animal, and also upon its physical condition. If the subject is emaciated and a probable victim of tuberculosis, the amount administered should be larger than that given to an apparently healthy animal." It is not necessary to go into the details of administration, thermometry, and complications, which are fully set forth; but it may be noted that up to the present time the injection can be utilized only for the detection of the disease, not for its localization. It is hoped that further observation will develop some method of ascertaining at least the comparative extent of the disease. A considerable

elevation of temperature after the injection, which, as is well known, is the important evidence of the existence of tuberculosis, may occur without the corresponding systemic manifestations observed in fever from other causes.

The report strongly favors the view that tuberculin is a very reliable agent for determining the presence of tuberculosis in cattle; that when properly prepared and judiciously handled it does not produce disease; and that it is the only known means whereby a positive diagnosis can be made in the early stages of the affection. So far from accepting the view that its employment will produce the disease in susceptible animals, it appears that some curative effects have been observed.

It is scarcely necessary to discuss further the question of the danger to the community from the unnoticed existence of tuberculosis in dairy-cattle. Indeed, statistical inquiries in some of the larger American cities seem to show that so general has become the information on this point that the use of milk as an article of food has been checked. The results in the Pennsylvania examinations confirm the view that a common mode of infection, especially in children, is through the employment of unsterilized milk from tuberculous cows, and an interesting case is noted by Dr. Pearson, which was reported at the Paris Academy of Medicine: "In a young ladies' boarding-school twelve girls presented symptoms of tuberculosis, and of these five died. Since all of these girls had healthy parents, and especially since all of them showed well-marked intestinal tuberculosis, the food was suspected. It was then found that the cow that had for years supplied the school with milk was tuberculous, and the autopsy showed that the viscera and the udder were badly affected." It is obvious that until a much more extensive examination of the dairies supplying our cities can be instituted there will be considerable liability to the distribution of tuberculosis in this manner. Official methods are not without disadvantage, and it is preferable that milk-producers and milk-purveyors should be brought to realize that they are responsible for the quality of the article which they furnish, and must institute careful, scientific inspection for themselves. The leaven of this unofficial supervision is already at work. We recorded some time ago the establishment under private auspices of regular and careful veterinary, bacteriologic, and chemic examinations of a certain dairy, and we are glad to learn that this system exists in various places. We are also pleased to note from a recent circular that a system of supplying Pasteurized milk, as distinct from sterilized milk, has been established. This milk is treated in a routine manner, so as not to be heated above 167° F., the operation being conducted in sealed cans. It is now recognized that milk sterilized by prolonged heating at the boiling-point of water is in many cases quite unsatisfactory as food for young children.

EDITORIAL COMMENTS.

The James E. Reeves Fund.—It gives us more than ordinary pleasure to announce the completion of the fund for the reimbursement of DR JAMES E. REEVES, of Chattanooga, Tenn., for the expenditure to which he was subjected in his manly and victorious fight against quackery in the defence of the suit of Amick *vs.* Reeves. The following is the bill of expenses:

Attorneys' fees	$ 100 00
Trip to Cincinnati	30 00
Stenographic report	35 00
Printing pamphlet	60 00
	$ 225 00

The contributions to the fund were as follows:

Dr. A. Vander Veer,	$ 35 00	Dr. A. A. Eshner,	$ 1 00
William Wood & Co.,	25 00	Dr. G. R. Fowler,	1 00
Dr. F. Forchheimer,	15 00	Dr. H. M. Haskell,	1 00
Dr. N. P. Dandridge,	11 50	Dr. W. T. Hope,	1 00
Dr. P. S. Connor,	10 00	Dr. Thomas Hubbard,	1 00
Dr. George M. Gould,	10 00	Dr. P. M. Jones,	1 00
Dr. William Osler,	10 00	Dr. G. W. H. Kemper,	1 00
Dr. J. F. Baldwin,	6 50	Dr. E. J. Kuh,	1 00
Dr. John A. Murphy,	6 50	Dr. H. A. McCallum,	1 00
Dr. A. B. Richardson,	6 50	Dr. G. L. Magruder,	1 00
Drs. Davis & Davis,	5 00	Dr. B. F. Miller,	1 00
Dr. John B. Hamilton,	5 00	Dr. D. E. Nelson,	1 00
Dr. J. H. Kellogg,	5 00	Dr. D. L. Page,	1 00
Dr. George Peck,	5 00	Dr. C. R Pickering,	1 00
Dr. Edmond Souchon,	5 00	Dr. Miles F. Porter,	1 00
Dr. R. J. Trippe,	5 00	Dr. R. T. Reeves,	1 00
Dr. J. T. Whittaker,	5 00	Dr. J. Robinson,	1 00
Anonymous,	4 00	Dr. P. D. Sims,	1 00
Thomas G. Allen,	2 00	Dr. Fred. B. Stapp,	1 00
Dr. S. Solis-Cohen,	2 00	Dr. S. W. S. Toms,	1 00
Dr. George E. Jones,	2 00	Mr. Fred. Volz,	1 00
Dr. N. W. Leighton,	2 00	Dr. Voigt,	1 00
Drs. Spiller and Zurmtey,	2 00	Dr. B. S. Wert,	1 00
		Dr. J. P. West,	1 00
Dr. C. G. Comegys,	1 50	Dr. J. E Copeland,	50
Dr. G. W. Drake,	1 50	Dr. S. A. Davis,	50
Dr. G. M. Ellis,	1 50	Dr. E. J. Doering,	50
Dr. W. F. Taylor,	1 50	Dr. E. B. Doolittle,	50
Dr. E. C. Anderson,	1 00	Dr. J. E. Miller,	50
Dr. Theodore G. Davis,	1 00	Dr. A. Tait,	50
Anonymous,	1 00	Dr. H. B. Tanner,	50
Dr. A. Cornish,	1 00	Dr. M. Walker,	50
Dr. Robert W. Earle,	1 00		
Dr. John Elfers,	1 00		$ 225 00

This list includes 65 contributions from 41 cities representing 17 States, the District of Columbia, and the Dominion of Canada.

The medical profession is to be warmly congratulated

upon the outcome of this whole matter, and it is a source of especial gratification that DR. REEVES has been so substantially supported by such a considerable number of men. We have here an evidence that the American medical profession is sound at heart, though its body may harbor some destructive parasites. How great and decisive was the victory may be appreciated when it is stated that the Amick Company had set apart the sum of $30,000 as a prosecuting-fund with which to punish in the courts every man who dared denounce its nefarious practices. The success of the suit of Amick *vs.* Reeves would have emboldened all forms of quackery and spread universal intimidation. As matters stand, the whole army of quacks has been brought under the lash and put upon the run. Let us hope that the victory may strengthen the hands of the trustees of the *Journal of the American Medical Association* and of the publishers of all medical journals in the exclusion of unethical advertisements, so that our current literature may be freed from the contamination of quackery.

In conclusion, we cannot forbear quoting a paragraph from a letter written by DR. REEVES:

"Such an unexpected reward for the simple performance of one's duty swells my heart with inexpressible gratitude. Indeed, now that I am growing old, it is worth more of consolation to me than all else I have earned in my struggles for usefulness in our adorable profession."

The Utilization of Waste Products.—There is a singular similarity between the ethicolegal and the sanitary problems of the body politic. In both the disposal of waste is a prominent factor. In the one realm it is a question of the treatment of the criminal and the pauper; in the other that of the pathogenic germ and the saprophyte with his culture-media. The earliest methods of management are identical in both cases. The criminal is knocked on the head or banished to the next county, or compressed into certain city purlieus, according to the magnitude of his crime; while the garbage is hidden under the rushes on the floor, thrown out of the door, or dumped in the nearest hollow. "Out of sight, out of mind," seems to be the motto of this stage.

Very shortly, however, it is discovered, by most vivid and bitter experience, that both the criminal and the garbage have a sort of "boomerang" quality, and are likely to "come back at" the community aforesaid, even from Botany Bay and the extreme limits of the back yard. So a system of repression and "deterring" is entered upon. Penalties are made still more severe; branding and mutilation are practised to make the evil-doer a living object-lesson of the unprofitableness of crime; long terms of imprisonment are imposed and the ends of the earth ransacked for places of penal exile.

Sewage is at the same period run into the nearest stream, or buried in the ground, or evaporated and burned; in a word, gotten rid of at any cost. Finally, it appears to dawn upon both legislators and sanitarians that, after all, there may be some value to the community in even these remnants; some sense of decency in the criminal, the pauper, the foundling; some commercial value in the offal and sweepings of our city streets. The latter are now used to grow the city's vegetables and fertilize and irrigate her waste lands, while the former are either made to earn their own living in some prison-factory or are reformed into useful members of the community.

Especially is this true of that large body of street-arabs, destitute children, and waifs and strays of every description that swarm in the slums of our large cities. These are no longer permitted to grow up in idleness, ignorance, and crime, to become enemies of the commonweal, for it has been proved beyond doubt that the young of the human species, however unfavorable its parentage, displays a strong tendency to revert to the sturdy, healthy, animal virtues of its prehuman ancestors. If it be given favorable environment, though there will be many a failure, in the great majority of cases it will respond promptly and permanently.

One of the first to grasp this truth firmly and effectively was the renowned Dr. Charles Barnardo, whose fiftieth anniversary is now being celebrated in London. Thirty years ago, a young medical student at a hospital in the very heart of the notorious Whitechapel district, he gave up his professional and social prospects to devote himself to the rescue of "these little ones." And how he has succeeded all the world now knows. "From a little one-roomed refuge his work has grown into dozens of institutions for sick, destitute, and neglected children of both sexes, where they are carefully schooled and trained; and thousands of what were once starving and homeless waifs are to-day doing their duty in that state of life, on both sides of the Atlantic, in which Dr. Barnardo's unceasing efforts have succeeded in placing them—an army of young, skilled mechanics, artisans, and domestics, of which any country might justly be proud." Of all the sick and neglected waifs that have been sent to him from almost every part of the world, not one has ever been refused admission to his homes. He had practically no money of his own with which to carry on the work, but his noble enthusiasm was infectious, and contributions poured in on all sides and from all classes. Such a man, indeed, deserves well of his country, and we are glad to note that a fitting testimonial is to be presented to him on the celebration of his coming anniversary.

The gain to the community from his achievements has been simply incalculable, and the State owes him as heavy a debt of gratitude as do the waifs and outcasts he has befriended. Probable paupers, possible criminals, and certain burdens upon the country have been converted into not only honest and self-supporting, but actually productive members of the body politic. It is a pleasant thought that it was while training himself for the noble profession of medicine that the inspiration came to him. The "medical student" bears a hard name, but here is one striking demonstration of how little he deserves it, to say nothing of a thousand less illustrious ones.

Act of the Pennsylvania Legislature relating to Contagious Diseases.—The Philadelphia Board of Health has just issued for the information of the public copies of the act of Assembly approved by the Governor June 18, 1895, and entitled "To provide for the more effectual protection of the public health in the several municipalities of this Commonwealth." The act relates entirely to the management of contagious diseases, and seeks to emphasize previous legislation on the subject. The penalty for failure to notify the health-board of the ex-

istence of cholera, smallpox, diphtheria, membranous croup, scarlet fever, typhoid fever, typhus fever, yellow fever, cerebro-spinal fever, relapsing fever, leprosy, varioloid or diphtheric croup, consists in a fine of not less than five dollars nor exceeding one-hundred dollars, and in default of payment imprisonment for not more than sixty days. The previous penalty had been a "fine not exceeding fifty dollars."

According to the new act, children living in a house in which a person has suffered from diphtheria, smallpox, scarlet fever, cholera, varioloid, diphtheric croup, membranous croup, leprosy, typhus fever, yellow fever, or relapsing fever, or children or other persons who have suffered from one of the diseases named, are forbidden attendance at school (public, private, parochial, or Sunday) for a period of *thirty* days after the discharge of the person last afflicted, either by recovery or death, or his removal to a hospital, and the thorough disinfection of the premises. Heretofore the period of time varied from two weeks for diphtheria to three weeks for scarlet fever. The new act not only makes thirty days the limit, but further provides that a city may designate that only a certain person shall issue a certificate allowing a child to return to school. In Philadelphia the medical inspector alone can issue the necessary permission.

In Section 19 we find that the health-authorities of a municipality are "authorized and empowered to establish rules and regulations regarding the isolation of persons," disinfection of bedding, fumigation, etc., "as they may, in good faith, declare the public safety and health demand, which rules and regulations they may from time to time alter and amend, and such rules and regulations shall have the same force and effect as though embodied in this act."

This gives the board of health of a city almost absolute power, whereas formerly it could only pass resolutions or have ordinances made through city councils. Under the new law any rule, relating to contagious diseases at least, can be put into operation without waiting for councils, mayor, or legislature, and the penalty for violating such a rule or regulation is the same as that given in the case of failure to report a contagious disease; although before such a fine can be levied the person accused must be convicted of the offence before a magistrate. The health-authorities of Philadelphia are the Mayor, who is *ex-officio* a member of the Board of Health; the Director of Public Safety, who is also *ex-officio* a member of the board and its president; and five other persons appointed by the Mayor and confirmed by Select Council; who constitute the Board of Health proper. The health-officer, though receiving his commission from the Governor of the State, is subject to the rules and regulations of the Board of Health, and is apparently subordinate to this board.

Under this new act the health-authorities, to cite an extreme case, would have the power to order the destruction of a house if they considered it infected; they could enter sweat-shops and destroy the articles found therein whenever they deemed it necessary and without compensating the owners of such articles for their loss. The provisions of this act relate to all the municipalities of the State.

—

Nordau's Disease.—We are decidedly averse to giving "that eminent degenerate," Nordau, so much of what he is desirous of having—free advertising—as is implied by a second allusion to his work, but we wish to speak of one aspect that has been admirably suggested rather than clearly pointed out in a volume of short stories, entitled *The Salt of the Earth*. We are also glad to say that these stories are by a physician, Philip Lafargue (his real name is Dr. J. H. Philpot), of London. The fundamental criticism of Nordau and Nordauism is that no one, however subtle and powerful his intellect, can ever reach *la vraie vérité*, the truest truth, by the intellect alone, and especially if what emotional bias he has is that of contempt and indignation. It is by the aid of sympathy that the most perfect mental picturing, the most complete mental diagnosis, can be made. The attitude of scorn of the object studied is a poor one, and leads only to partial and imperfect results—just such results as Nordau has reached. Not only this, there is illustrated in his book the fundamental intellectual sin of most of modern literature—the use of intellectual power selfishly, not to present the uncolored truth, but to produce intellectual fireworks, to flash and dazzle, to attract attention to self. Already we hear that the learned author is under contract to write a novel and also a play. There yet remains the still more damaging point of criticism, the sorry fact that the author, who is a physician, not only does not study the disease, let us call it with peculiar appropriateness, *Nordau's disease*, scientifically, *i. e.*, without bias or coloring, without propossession, but it is most certain that from the beginning his results have been worked up to, and that violence has been done to his facts in order to make them prove his desired conclusion. The idea of calling Ruskin and Wagner and Rosetti degenerates! This is one of many instances in which critical vanity and pessimistic egotism peep about under the huge legs of genius to find themselves a dishonorable grave. Even Rossetti has written single stanzas worth more than the entire volume of his scorner. Finally, to cure not to curse, to sympathize not to anathematize, is the ideal of the true physician. This, *Doctor* Nordau has not chosen to do; but this Dr. Philpot has chosen, and we write to commend the book that is not the product of a brain cynical and pseudo-scientific, and that therefore needs all the more to have its merits praised.

—

The Management of Infants during the Heated Term.—The Board of Health of Philadelphia has published for distribution a pamphlet giving special rules for the management of infants during the hot season, based upon recommendations made by the Philadelphia Obstetrical Society a number of years ago. These rules are very simple, and should be familiar to every mother, yet many do not possess even a tithe of this knowledge. Rule 8 directs that "if the cow's milk is not known to be pure no water should be added." It would have been better to insist upon the use of pure milk, and to have secured such assurance by having samples of the milk tested free of charge under the supervision of the health-authorities. While the term "sterilization" is not specifically used, the directions to "scald the milk as soon as it comes and to put away in the coolest part of the house—on ice if it can be afforded"—are probably as plain as can be given in a statement intended for universal comprehension. It might not have been out of place to state in a few terse sentences in what ways milk is usu-

ally contaminated, in order that these several sources might be avoided. The reference to condensed milk made in Rule 9 is in disregard of recent investigations upon this subject; it would have been better to recommend instead some other modification of cow's milk.

There is a need for informing the public through some official source how to put into practice recognized sanitary principles, and the Philadelphia Board of Health is to be commended for its efforts in this direction.

In the absence of medical men from boards of health, it would, perhaps, be well for such boards to invite from time to time suggestions from representative medical bodies as to the means to be adopted by the community to prevent disease, and such recommendations should be couched in simple and unambiguous language, and printed for general distribution. The Philadelphia Board fortunately includes two medical men, one of whom is its president.

Traffic in Misery and Folly.—There are many great advertising dispensaries and cure-alls. None is more business-like than the one to which we wish to refer. This concern advertises in a systematic and orderly manner in the secular and daily press of the country. It has a large corps of letter-writers and correspondence-clerks. In its safes it has preserved the letters and confessions of almost a million miserable and foolish men and women. This correspondence is tabulated and is followed by a record of the treatment, and, what is of more moment, of the contract and the moneys paid on it.

Not long ago a like concern failed in a city 800 miles distant. Among the most valuable assets of the defunct concern were similar records of 200,000 dupes. These the first great business-house referred to bought of a speculator, agreeing to pay fifty cents apiece for each new name of a living person. In checking up the lists, 60,000 of the 200,000 were found to be on their books already.

Perhaps all readers of the newspapers have noticed an advertisement for a lock of hair, upon the receipt of which the advertiser agrees to tell the sender's fortune and cure his disease. The author of this "fake" lately retired from business, and his correspondence, including over 600,000 locks of human hair from as many heads, was sold to an advertising concern.

These are simply samples of business principles applied to medicine.

Surgical Shock as a Cause of Death in Women.—Among the causes of death mentioned in the report of the Registration Department of the Philadelphia Health Office for 1894, "surgical shock" is credited with seventy-five deaths; of which number twenty-one occurred among males and fifty-four among females. Examining the reports of previous years we find:

In 1890 surgical shock caused the death of 6 males and 12 females; 1891, 9 males, 21 females; 1892, 8 males, 43 females; 1893, 19 males, 43 females.

Whether women are more frequently operated upon than men or whether the operations they undergo are more liable to result in shock, or whether women because they are women are predisposed to shock, are questions that naturally suggest themselves after glancing at the statistics cited. Perhaps the gynecologist can throw some light on the subject. But whatever the explanation, it is desirable that the return of death should mention the kind of operation from which the shock resulted, and that the term "surgical shock" as a cause of death be relegated to the limbo of insufficient medical terms, as "heart-failure" and "apnea" have been.

SELECTION.

SUICIDE.

Professor Sikorski, of the University of Kief, writing in the *Kievlianin* upon the psychology of the Russian people, brings forward some interesting statistics concerning the frequency of suicide in the different nations of Europe. According to these figures, the death-rate from suicide per million living is in Saxony 311, in France 210, in Prussia 133, in Austria 130, in Bavaria 90, in England 66, while in Russia it is as low as 30. Further, it is found that during the last thirty years the suicide-rate has in Russia remained stationary, while in all other European countries it has increased by 30 or 40 per cent. The exact significance of figures such as these, relating to so complex a phenomenon as suicide, is not easily brought out. Few, however, will be disposed to question the assertion that much of the explanation of the low rate in Russia is to be found in the patience and long suffering of the Russian peasant under even the worst misfortunes. Among other characteristics Professor Sikorski also finds a certain indecision of character which fears to say a word or do an action which shall not admit of retreat or withdrawal. Crime is comparatively rare in Russia; thus, the number of persons tried for murder per million living in the year 1887 was in Italy 96, in Spain 55, in Austria 22, in France 14, in Russia 10, in Germany 9, and in England only 6.—*The Lancet.*

REVIEWS.

The Elements of Pathological Histology, with Special Reference to Practical Methods. By Dr. Anton Weichselbaum, Professor of Pathological Anatomy and Director of the Institute of Pathological Anatomy in the University of Vienna. Translated by W. R. Dawson, M.D. (Dublin), Demonstrator of Pathological Anatomy in the Royal College of Surgeons, Ireland, etc. 8vo, pp. xv, 456. London and New York: Longmans, Green & Co., 1895.

Those unfamiliar with German are to be congratulated on being provided with such an admirable translation of Professor Weichselbaum's *Grundriss der Pathologischen Anatomie.* Few and unimportant changes have been made in the original, though some additions have been incorporated in the present work. Professor Weichselbaum is deservedly recognized as one of the foremost pathologic anatomists of the world, and this product of his labors must be viewed as an authoritative expression of opinion upon the subjects with which it has to deal. An industrious worker, a careful observer, a wide reader, a progressive and original investigator, a thorough student and capable teacher, a fluent and

easy writer, we have combined the elements essential for successful authorship. This work has been prepared principally for the beginner and the student, and deals in a measure both with the theoretic and the practical aspects of pathologic anatomy.

The translation has been arranged into three parts: the first dealing with general methods of investigation, the second with general pathologic histology, and the third with special pathologic histology. Part I includes a consideration of both histologic and bacteriologic methods of investigation. Part II retrograde changes in tissue; progressive tissue-changes; inflammation; infective granulation-tissue tumors; tumors or new-formations; the parasites, animal and vegetal, macroscopic and microscopic. Part III deals successively with the blood, the circulatory apparatus, the spleen, the lymphatic and thyroid glands, the suprarenal capsules, the digestive apparatus, the liver, the bile-ducts, the pancreas, the respiratory apparatus, the urinary apparatus, the generative apparatus, the nervous system, the organs of locomotion, the skin, the eye, and the ear. An index of fourteen pages facilitates reference. The work is in all respects a most admirable one and deserving of the warmest praise, the translation not less so than the original. The toned paper is heavy and of excellent quality, the type is large and clear and well arranged, and the illustrations, of which there are more than two-hundred, together with eight plates, drawn principally from original preparations, are artistic and accurate. Altogether, the work deserves a cordial reception, and should prove of the utmost service, not only to those for whom it was principally written, but also for the great body of practical physicians interested in the scientific status of their profession.

TRANSACTIONS OF THE VERMONT STATE MEDICAL SOCIETY FOR THE YEAR 1894. Published by the Society.

THE Vermont State Medical Society enters on its eighty-second year of existence with a membership of 175. This volume of its *Transactions* contains thirteen papers read at the annual meeting of 1894. The address by the President, Dr. A. B. Bisbee, is in the form of a paper on the "Conditions Which Favor Tuberculous Infection," and contains statistics gathered from life-insurance material. Dr. J. B. Brewster reports an epidemic of typhoid fever in the town of Windsor, which affected 10 per cent. of the inhabitants (130 cases). The source of contagion was traced to the water-supply, which the "village voted to discontinue," and it now has pure water. Dr. Caverly gives an account of an epidemic of acute anterior poliomyelitis which was confined to the Otter Creek Valley. The majority of children affected were under six years of age; 126 cases are analyzed. F. A. Rich, V. S., M.D., in a paper on "Tuberculosis in the Lower Animals," gives the results of tuberculin-tests in Vermont cattle and in the cattle of other States.

THE INTERNATIONAL MEDICAL ANNUAL AND PRACTITIONERS' INDEX. A Work of Reference for Medical Practitioners. New York: E. B. Treat, 1895.

THIS work, which is in the thirteenth year of publication, is an annual review of the progress of medicine, with special reference to the treatment of disease, condensed in this instance to fill one volume of 648 pages, and edited by thirty-seven British and American medical men, who also contribute a few original articles. Part I is called "A Dictionary of New Remedies," Part II "A Dictionary of New Treatment in Medicine and Surgery," and Part III consists of a review of sanitary science, a review of pharmacy, and contains a small list of new inventions, and a very superficial list of "the principal medical works" published during the year 1894. In order to show "his consideration for all schools" the publisher includes in the list of books a half-dozen or more homeopathic treatises and pamphlets.

Twenty-four full-page plate illustrations accompany the text, although seven of these serve to illustrate an article on eyesight and school-life and are evidently introduced simply to render the work attractive. There is much, however, in the book to recommend it to those who desire a partial index of the medical literature of the year.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF CALIFORNIA. 1895. Pp. 441. San Francisco: W. A. Woodman & Co.

THIS volume contains forty papers and committee-reports on special subjects. The articles on Medical Education, the Opium-traffic, and Quackery in Genito-urinary Diseases contain some interesting features. An extravagant paper by C. G. Kuhlman, entitled "The Status Præsens of Inherited Tuberculosis," undertakes to point out the exact nature of the laws required to limit if not to eradicate "tuberculosis, which in the author's opinion is in nowise "contagious, infectious, or dangerous to the public health." The Board of Examiners report 305 applications acted upon, of which 9 were refused. The Society contains 340 active members, and this present volume is the twenty-fifth of its *Transactions*.

THE RETROSPECT OF MEDICINE. By JAMES BRAITHWAITE, M.D., London. Volume cxi. July, 1895. American edition. New York: G. P. Putnam's Sons.

THIS half-yearly compend of medical progress contains a synopsis of a considerable number of articles in the various branches of medical science that have appeared in the medical journals in the last six months. A publication that is in its fifty-fifth year must be of some use to the medical profession. A condensed summary every six months of what the medical world is doing ought to keep the busiest practitioner well informed, and Braithwaite's retrospect serves such a purpose.

CORRESPONDENCE.

OTO-MASSAGE.

To the Editor of THE MEDICAL NEWS,

SIR: While hesitating to differ with so eminent an otologist as Dr. C. H. Burnett, I cannot refrain from calling attention to some points that he has overlooked in making sweeping assertions in regard to oto-massage in your issue of August 10, 1895. He speaks of direct pressure on the membrana tympani bruising and wounding that structure. This reminds me of inquiries as to

whether I had ever ruptured the membrana tympani in practising pneumatic massage, or had hemorrhage or syncope follow. Now these results and "bruising and wounding" the drum-membrane can only follow that which might be more properly classed as orthopedic surgery than as pneumatic massage. I have seen a mutilated drum-membrane as the result of rough usage of the Delstanche, but never from properly applied pneumatic massage.

Another thing: Dr. Burnett condemns all forms of "direct pressure" on the membrana tympani, and doubtless no condemnation can be too severe for the brutal stabbing at this delicate structure with probes or solid bodies of any kind. But a properly constructed pneumatic masseur, of which there are several, never produces any pressure on the drum-membrane. Such an instrument will first exhaust and then release the air confined in the external auditory meatus—never compress it. Furthermore, the action is never sufficient to do the slightest injury, never more than enough to give a slight, but perceptible, motion to the membrana tympani if observed through a Siegle speculum. Sittings should never be longer than thirty seconds nor oftener than thrice weekly. Used in this way no harm can result, and I can exhibit a number of cases in which benefit to tinnitus and hearing-distance is unmistakable in extent and permanency.

A man who has no more respect for a beautiful and delicate structure like the human ear than to go stirring around in the auditory canal with a probe and treating a middle-ear sclerosis as an orthopedic surgeon would a fibrous ankylosis of the knee-joint will doubtless never get good results from pneumo-massage.

This matter of pneumatic massage reminds me of those obstetricians who used to blame ergot for lacerating the cervix and perineum, yet they could never be induced to give less ergot than two drams of the fluid extract; often more. If they had tried less heroic therapeutics, the results would have been better and no harm would have been done.

The great trouble has been that oto-massage was widely heralded as a wonderful and infallible remedy for every case of deafness. When this occurs with a remedy but one result can follow: Up like a rocket and down like the stick. Instead of selecting the cases to which the remedy is adapted it is applied to all cases that come along. Any good the remedy may do is altogether lost sight of because too much is expected and required of it, and it is put to a test that no remedy will stand. Certainly Politzerization will not stand the tests to which any new remedy is put. If any otologist gets *permanent* substantial benefit from the Politzer in 40 per cent. of all his sclerotic middle-ear cases, he is more fortunate than I have been. Excision of the membrana tympani, and of two or all of the ossicles, does not yield a higher percentage of benefit. Then why look for pneumatic massage or any other new procedure to perform miracles? The air-douche of Politzer has its sphere of usefulness, but no one looks for it to benefit all cases, nor half of them.

Yours truly,

CHEVALIER JACKSON.

PITTSBURG, PA.

APOMORPHIN IN THE TREATMENT OF OPIUM-POISONING.

To the Editor of THE MEDICAL NEWS,

SIR: As I frequently see in reports of cases of opium-poisoning that apomorphin is still used for its emetic effect in such cases, I feel called upon to utter a word in protest against what I believe to be a very dangerous as well as useless practice. My experience with it is limited to one case.

The patient, a woman, had taken a large quantity ot morphin and was so profoundly narcotized when I saw her that respiration had to be stimulated and later sustained altogether artificially. Sending a messenger hurriedly for a stomach-tube, battery, and other necessaries, and an hour later another messenger after the first (neither of whom returned), I finally grew desperate and gave the patient gr. ⅙ of apomorphin hypodermically. The heart's action, which had been fairly good up to this time, quickly thinned away, and in fifteen minutes the patient was dead.

Up to the time of seeing this case I had given the subject very little thought and merely had a vague fear of the depressing action of apomorphin on the heart. Its action here, however, together with some experience in its use as an emetic in cases of alcoholic intoxication, has convinced me of both its inutility as an emetic and its dangerous, nay, its almost necessarily fatal, effect as a heart-depressant in subjects already narcotized by opium or alcohol.

In the first place, emesis is essentially a muscular act and cannot possibly occur without vigorous contractions of the muscular coat of the stomach, together with fixation of the diaphragm and abdominal muscles—conditions impossible to effect in that state of extreme muscular relaxation which accompanies narcosis from opium or alcohol.

In the second place, the effect of apomorphin as a heart-depressant is most profound and unmistakable.

One-sixth of a grain given to a strong, muscular man suffering from acute maniacal alcoholic intoxication ("fighting drunk"), with the attending muscular activity and high arterial tension, will in ten minutes so prostrate him that he will be too weak to raise his head, and the excited heart will have so changed that the pulse can hardly be felt. A drug that will so quickly produce such extreme exhaustion must, it seems to me, be almost necessarily fatal if used in cases of opium-narcosis, in which the heart's action is already depressed to the danger-point.

Respectfully,

GEORGE S. BROWN.

BIRMINGHAM, ALA.

A DEFINITION OF NIGHT-TIME.

To the Editor of THE MEDICAL NEWS,

SIR: Allow me to call your attention to Chapter 85, as enacted by the Legislature of Wisconsin and approved March 23, 1895, as it may be of importance in county bills, poor bills, etc. If it can be made effective in regular practice, it will be a veritable boon for physicians whose work in the winter often accumulates toward evening.

Yours respectfully,

M. IVERSEN.

STOUGHTON, WIS.

No. 86 S. Published March 27, 1895.

CHAPTER 85.

AN ACT to define the time "night-time" when used in any statute, ordinance, indictment, or information.

The people of the State of Wisconsin, represented in Senate and Assembly, do enact as follows:

Section 1. The time "night-time" when used in any statute, ordinance, indictment, or information in this State shall be deemed to be the time between one hour after the sunsetting on one day and one hour before sunrising on the next day; and in all cases the time of sunsetting and sunrising shall be ascertained according to mean time in the place where the term may be used, as given in any published almanac.

Section 2. This act shall be in full force and effect from and after its passage and publication.

Approved March 23, 1895.

VITAL STATISTICS.

To the Editor of THE MEDICAL NEWS,

SIR: I note an editorial reference in THE MEDICAL NEWS of August 17, 1895, p. 180, to the death-rate of Denver and to the probability of the population being overestimated. I wish to explain that in estimating the increase of population of the city I have added each year a number equivalent to the annual increase during the ten years elapsing from 1880 to 1890; this made our estimated population at the end of the year 1894 about 135,000. At that time there were added to the city by annexation the towns of North Denver, South Denver, and Harman, together with adjacent and intervening suburban districts, containing altogether about 10,000 persons. This seems to me to justify the estimated population of 145,000, upon which our statistics are at present based. An analysis of the figures given in our monthly reports will show that the percentage of deaths from the causes usually held to be preventable is quite low; this, together with the large percentage of adults composing our population, satisfactorily explains the low death-rate of Denver.

Very respectfully,

WILLIAM P. MUNN,
Health Commissioner.

DENVER, COL.

NEWS ITEMS.

The Number of Medical Students at the German Universities.—The whole number of medical students in the universities of Germany during the summer semester of 1895 was 8030, of whom 1209 were at Munich, 1080 at Berlin, 707 at Würzburg, 617 at Leipzig, 443 at Freiburg, 406 at Greifswald, 399 at Kiel, 338 at Breslau, 300 at Strassburg, 275 at Heidelberg, 246 at Königsberg, 245 at Marburg, 241 at Halle, 220 at Göttingen, 215 at Tübingen, 195 at Jena, 137 at Giessen, and 101 at Rostock. Thus Munich stands first numerically, and this superiority is due to its greater attractiveness for non-Bavarians, of whom there were 792, whereas at Berlin there were only 298 non-Prussians. During the winter semester of 1893–94 in German universities, 1406 students received, on examination, the degree of M.D., of whom 100 were pronounced "sehr gut" (very good), 928 "gut" (good), and 378 "genügend" (sufficing). Of the first class there were at Leipzig 14, and of the second class 146 out of 201; at Munich, 12 and 111 out of 166; at Würzburg, 11 and 96 out of 135; while at Berlin there were none of the first class, and 111 of the second out of the entire number, 169. These statistics would imply that the examination for a medical degree is more rigorous at Berlin than at the other German universities—assuming, of course, equal competence and diligence on the part of the students.—*Corresp. N. Y. Evening Post.*

Malarial Hematuria.—A committee of the Tri-state Medical Society of Arkansas, Mississippi, and Tennessee, consisting of Drs. William Krauss, G. B. Malone, and G. G. Buford, of Memphis, Tenn., and Dr. R. W. Barton, of Marion, Ark., desires to make a complete report on the subject of malarial hematuria at the meeting of the society in Memphis, in November next, and requests information upon the following points: 1. Number of case. 2. Age, color, sex, etc. 3. Previous history. 4. Sanitary surroundings. 5. Kind of drinking-water. 6. Season of year. 7. Is malaria abundant at the time, and in what form? 8. Is malarial hematuria abundant at the time? 9. What type of malaria, if any, preceded the attack? 10. Had patient taken quinin, and how much? 11. Symptoms, character of urine, etc. 12. Therapy. 13. Was blood examined? 14. Termination. 15. Post-mortem appearance. 16. Is it patient's first attack?

Dr. G. W. H. Kemper, of Muncie, Ind., celebrated on August 19, 1895, the thirtieth anniversary of his entrance on the practice of medicine. At a reception held by Dr. Kemper numerous toasts were made and appropriately responded to; and the doctor was made the recipient of a gold-headed cane presented by his medical friends. Dr. Kemper was born in Rush County, Ind., in 1839, and was graduated in medicine from the Long Island College Hospital in 1865. He rendered active service in the War of the Rebellion, and he has held numerous public and professional positions of distinction.

Major Thure Brandt, a Swedish officer and the originator of pelvic massage as a gynecic therapeutic measure, died recently at the age of seventy years.

Correction.—On fourth line from top, second column, page 243, of THE MEDICAL NEWS, August 31st, "1 per cent." should read "2 per cent."

ORIGINAL ARTICLES.

A STUDY OF MUSCÆ, WITH SUGGESTIONS AS TO THE PHYSIOLOGY OF INTRAOCULAR NUTRITION, THE ETIOLOGY OF CATARACT, GLAUCOMA, ETC.

BY GEORGE M. GOULD, A.M., M.D.,
OF PHILADELPHIA

INTRODUCTORY. Subjective visual sensations have not been studied by scientific methods to that extent that their importance warrants. That these phenomena are very common (occurring doubtless to every person), of very great variety, of physiologic significance, and that they are transitory symptoms of many diseases, and unexceptional or continuous symptoms of others—these facts have long been known, but their import has hardly been realized. The recent admirable study of one variety, scotoma scintillans, by Gowers,[1] is, so far as I know, almost the first, certainly the first scientific attempt to classify one genus of these phenomena. Before reading Dr. Gowers' lecture I had carried out the experiments (if they may be so dignified) and made the notes to be described hereafter. Encouraged by the illustrious example, I am moved to set forth a few observations that may be suggestive and helpful to others in their better studies.

CLASSIFICATION. Until more accurate observations have been made, any attempted classification and theory of the phenomena in question will be inexact and incomplete. So soon as possible some sort of grouping and ordering should be made, however tentative it may be. But any such classification at once presupposes a theory or doctrine assumed concerning them, and this assumption is, of course, met by the evident fact that, scientifically, we know too little concerning them to permit of any but a loose and conjectural theory. In a rough way, however, with some doubt and qualification, we may say that all the phenomena in question arise or reside in organs more or less localizable—*i. e.*, they are either:

1. *Peripheral*, originating in the globe of the eye (including the optic nerve), or in adjacent and related organs, as, *e. g.*, muscæ, pressure-phosphenes, etc.
2. *Central*, originating in the cerebral centers where optic-nerve impulses are transformed into visual sensations, as, *e. g.*, scotoma scintillans, phosphenes from occipital traumatism, etc.
3. *Combinations of the two.*
   - *a.* Peripherocentral, primarily or preponderatingly peripheral.
   - *b.* Centroperipheral, primarily or preponderatingly central.

In a strict and physiologic analysis it may be true that every visual sensation requires the synchronous cooperation of both the peripheral and the central mechanisms. In those most manifestly central the mind imperatively locates a corresponding object outside of the body, and even a corneal opacity requires the central mechanism to become subjectively manifest. And yet the classification has a certain validity readily understood.

NOMENCLATURE. This also is in a state of chaos. It would be easy to devise a systematic nomenclature. I have, indeed, busied my fancy with one—and present it with little confidence, because such Minerva-born systems are generally stillborn. The world loves its old foolish names of things, and with most people habit is fate. It would seem a clarifying and labor-saving device to designate somewhat as follows:

SUBJECTIVE VISUAL SENSATIONS.

PHOSES: Light-sensations of whatever kind or color, of a positive nature.

APHOSES: Absences or interruptions of light-sensations, scotomata, shadows, whether formless or of more or less indeterminate form.

PERIPHEROPHOSES: Phoses originating in the peripheral ocular mechanism.

CENTROPHOSES: Phoses originating in the central ocular mechanism.

PERIPHERAPHOSES: Aphoses originating in the peripheral ocular mechanism.

CENTRAPHOSES: Aphoses originating in the central ocular mechanism.

CHROMOPHOSES: Colored phoses—and, if desirable, subvarieties, to wit:

- *a. Erythrophoses*, Red Phoses.
- *b. Chrysophoses*, Orange Phoses.
- *c. Xanthophoses*, Yellow Phoses.
- *d. Chlorophoses*, Green Phoses.
- *e. Cyanophoses*, Blue Phoses.

[1] Lancet, Nos. 3747 and 3748. The Bowman Lecture: On Subjective Visual Sensations.

f. Indikophoses, Indigo Phoses.
g. Ionophoses, Violet Phoses.

Without driving the name-making instinct to name-mania, the modifications and qualifications of all subjective visual sensations may be adapted to the terms given, as, *e. g.*, stellate, fiery, darting, stationary, annular, beaded, fortification phoses, etc. The word *spectra* should not be used here, as it has other definite and sufficient uses.[1]

PERIPHERAPHOSES may, of course, be due to opacities of the cornea, aqueous humor, lens, vitreous, or retina. The most constant, commonly observed, and often bothersome of these is the class called muscæ volitantes (better, simply muscæ), or, perhaps, muscal peripheraphoses.

OBJECTIVE CONDITIONS FOR STUDYING MUSCAL PERIPHERAPHOSES. In the summer of 1895 I lived upon a mountain 4000 feet above sea-level. In looking at the panorama of mountains and sky stretched before me I found that my never-absent *mouches volantes* were often outlined with surprising clearness, and were far more numerous than I had supposed. I found that the background of a sun-illumined bank of clouds brought them out with unsuspected sharpness. I have spent many hours in studying them. The dull white, horizonless, cloudy, misty, or smoky sky, with no definite object to fix the attention, below, around, or above, is, therefore, the best objective condition for the study proposed.

SUBJECTIVE CONDITIONS. The principal of these is good health (as that is essential to the highest retinal sensitiveness), patience, dexterity of ocular movements, good visual acuteness (my own is 20/10), and experience in catching infinitesimally slight visual sensations, and especially those intermediated by peripheral portions of the retina. The less direct sunshine there is the wider the pupils, and hence the larger the "field of operation," although the clouds should be bright with diffused sunlight. A large measure of success is doubtless dependent upon long education of the extramacular portions of the retina, and the ability to study objects focused there. But I shall describe a most valuable means of largely obviating the necessity of this peripheral-field study, and one also that has, I think, considerable significance in other directions. This method is one that for want of a better name I have called—

OCULAR BALLOTTEMENT. It is almost needless to explain the principle of physics underlying the experiment of ballottement as practised by obstetri-

[1] A PERSONAL OBSERVATION AS TO "FORTIFICATION"-CHROMOPHOSES. Dr. Gowers has wisely suggested the collation of personal experiences, and although my object in this writing is to express some thoughts as to one variety of "peripheraphoses," commonly called *muscæ volitantes*, which should be conveniently contracted to *muscæ*, I shall take occasion to say parenthetically that I have been subject all my life to attacks of fortification-chromophoses, or scotoma scintillans. These seem to have no definite periodicity. Sometimes I may go a year with none, and sometimes I may have several attacks in as many weeks. I do not remember to have had two attacks on the same day. I can trace them to no cause either in the general health, or in special conditions, of study, etc. I think being in bright sunlight has sometimes been an immediate or cooperating factor in bringing on an attack. More often I have noticed that after walking rapidly in sunlight the sudden entrance into a dark hall or room would produce what might be called a pseudo-attack—an aura, or intimations of the same, dim scintillations, indistinct chromophoses, but lasting only for a few seconds or a minute.

The genuine attack begins with the dimmest fluttering, as if of some indeterminate thing at the periphery of the field of vision, usually on the right side, a little north of east, let me say, or sometimes due northeast. This fluttering gradually approaches the center of the field, but never reaches it, and as it approaches it becomes both more distinct in form and more definite in chromatization. It takes from five to ten minutes before the acme of the attack is reached, and as long for the subsidence, which last, as to color, location, etc., is the exact reverse of that of the ascending process. At the period of greatest intensity the chromatization is not definite; *i. e.*, I cannot clearly distinguish definite colors; this may be due to the rapidity of the fluttering or scintillating movements, which I estimate as about six or eight a second. This vibratory or fluttering movement is about uniformly rapid from the beginning to the end of the attack, and is about the same in all attacks.

The predominating colors, perhaps, are, in order of prominence, yellowish-white, reddish-yellow, and a dark neutral-tinted or aphosic line that forms the most clearly distinguished central part of the "fortification"-figure. But the angles of my fortifications are never sharply acute; they are usually about right-angled, or slightly obtuse. Sometimes in their approximation to the center of the field of vision the widening fluttering lines will show a distinct curvature about it, but neither the straight nor the curved series of angular chromophoses usually pass beyond the hemianopic vertical line into the left hemisphere. There are no sequelæ whatever, no migraine, no headache, or other uncomfortable symptom.

During the paroxysm, although the chromophoses do not seem to attack the macular vision directly, I somehow find it impossible to continue reading. I have a difficulty in determining or describing the reason for this. By an effort of will I can see the printed words, at least temporarily, but they become blurred or in some way indistinct, and it becomes extremely difficult, though not painful, hardly even uncomfortable, to continue. The waving and quivering of that tormenting flag, so very close to the eye, is unendurable, and I lie down or walk about until it all passes away. Position of the body, or brisk exercise—nothing seems to influence in the least the ordered march of events. The process seems to appear when it will, without discoverable cause, and carries out its kaleidoscopic program without regard to any physiologic influence.

I may also allude to a variety of phoses that I have observed a thousand times, but that I have not seen described. In looking at a uniformly well-lighted blue sky I can, by careful and continuous indeterminate observation or interspace-fixation, bring to view numberless pin-point phoses, not very sharply and definitely outlined, but still clearly seen, appearing and disappearing with almost lightning-like rapidity, and quivering or darting throughout the central visual field. I attribute these to the commotion set up by the diffused strong light-stimulus in the pigmentary receiving-substance of the retina, these individual dot-phoses or peripherophoses being the idiopathic response of particular retinal nerve-ends or elements to the general stimulus. These definite phoses are preceded by a period of indeterminate quivering of the air, as it were, or of something so near nothing that it is beyond recognition or description.

cians. If a body of slightly greater specific gravity than the liquid in which it is submerged is, by a fillip, thrown to the surface or upward, it will slowly settle back again to the bottom. In cases of chronic choroiditis shreds of exudate floating in a liquid vitreous can, by a little fillip of the eye by the patient (first upward and then suddenly halting at horizontal fixation), be seen with the ophthalmic mirror descending to the lower part of the eye like snowflakes in the night as seen from a window. The rate of downward movement will, of course, depend upon the relative densities of the liquid and the opacities.

From time immemorial muscæ have been described as shadows of retinal vessels and vitreous cells directly *in front of the retina* (*not* directly in front of the *vitreous*), located at one side of the fixation-point, so that they continually elude direct fixation by a will-o'-the-wisp movement ever further and further as one seeks to transfix them with the optic axis. A few experiments with ocular ballottement will show one that these are not fixed particles, but that they are bodies floating in a liquid medium, and thrown by motions of the eyeball upward or about, to settle, if permitted, at the most dependent portion of the eye. This can be demonstrated, while sitting in the usual position, by a rapid whirl of the eyeballs, suddenly again resting at horizontal fixation. The swirl of the muscal bodies will now be seen to follow the previous circular motion of the liquid, curving as they fall. One may then lie down on the right side with the axis of the body and head horizontal: the particles now fall, after ocular ballottement, toward the right temple or the ground. By lying on the left side the same facts, *mutatis mutandis*, are shown. By a very sudden and energetic jerk of the eyes downward, arresting the movement very sharply and suddenly, one may get a positive rebound from the bottom of the chamber up to the line of visual perception. But the most convincing and instructive experiment is to lie flat on one's back, without pillow and with the chin slightly elevated; by dexterity both in movements of the head and of the eyes, one is then able to bring any one of these muscæ into the center of the field, and poise it there, as a juggler adjusts a whirling plate above his head. Thus to bring any one of many muscæ haunting the periphery into the line of macular vision, and to hold it steadily there while gazing at it, will require considerable experimentation with the ocular fillip, and with delicate poising or adjustment of the head. By alternately closing one eye and then the other one may observe in which eye a group of muscæ is located.[1]

[1] I have been able to observe muscæ through the closed lids, the eyes being directed toward brilliant light. I have also studied them face downward, overlooking a neutral-tinted illumined porch-floor, but the experiments brought out no significant facts.

ACTION OF ACCOMMODATION UPON MUSCÆ. If while holding an aphose thus in unstable but continuous fixation, a sheet of gray paper is interposed within about twelve inches of the eyes, at once what was a very indeterminate, formless, or dimly seen shadow is minimized in size, but correspondingly definitized in outline and characteristics according to well-understood optic laws. At the same time the fact will be noted that when deftly done the act of accommodation does not *per se* squeeze, or deport the object aside. I infer from this that wherever the liquid chamber is located the bulging of the crystalline lens does not greatly displace the particles of the liquid and of the contained muscægenetic particles. As I shall try to show, this liquid chamber (let us for the time name it the aqueovitreous chamber) is, I believe, located immediately behind the lens, and I at first thought that the fact that the particles do not move by the act of accommodation argued against the theory of this location of the chamber, because it would seem that the backward bulging of the lens would somewhat squeeze aside the particles in the base of the cup. I conclude, however, that the chamber is located as described, and that the non-movement of the particles in accommodation is due to the fact that the chamber is *full* of liquid and under pressure as much, of course, as all intraocular humors, and that the slight backward thrust or compression would not, therefore, displace the particles in the central portion, or that pierced by the visual axis. Besides this, the bulging of the circumjacent ciliary muscle would equal and neutralize any tendency of the lens-movement to displace them.

THE LOCATION OF THE AQUEOVITREOUS CHAMBER. The motion of the muscægenetic particles after the fillip of ocular ballottement determines the location of the aqueovitreous chamber. Objectively in choroiditis we can see the opacities descend after the upward glance of the patient's eye, or rebound from the bottom of the chamber when a sharp downward sweep is suddenly arrested. Subjectively we may observe the same phenomenon in the case of physiologic peripheraphoses or muscæ. But in the latter instance we can use the slightest fillip, a mere hint of short upward-glancing, and observe the resultant upward jerk of the particles, to be followed, of course, by their slow fall if the gaze is then kept steady and unmoved. Sometimes the particle is situated laterally in the field, and the motion of the eye to see it continuously displaces it further laterally, but the usually downward tendency can be shown by steadily holding the eye quiet. It certainly falls by gravity, out of reach of sight, in the dark parts of the chamber. I have rarely noticed any appearance disproving that the particles are not freely mobile, except that the larger or more swollen strands, and especially

the tangled masses of the same, are often more difficult to manage, seem to adhere to the walls of the chamber, etc. These facts necessarily locate the chamber in front of the vertical equator of the eye. If the chamber were posterior to the equator, an upward glance would throw the particles downward. (This fact may serve as an aid in localizing the position of pathologic vitreous opacities.) From readily recognized reasons, needless to recapitulate, the location of the aqueovitreous chamber containing the muscægenetic particles in suspension must be between the vitreous body posteriorly and the lens, its ligament, and the ciliary body, anteriorly. It may be said if such a "chamber" existed in this situation anatomists would long ago have demonstrated its existence, but in reply it need only be said that the mere fact of opening the globe destroys the space, and the extremely thin film of liquid in the unwalled space disappears unnoticed. Attention to it will, I am sure, result in methods of demonstrating its existence with the naked eye or the microscope.

CHARACTER OF THE MUSCÆGENETIC PARTICLES. In my own case the most conspicuous of these particles are what I have called cellular; *i. e.*, aphosic globes or ring-like appearances, sometimes nucleated (with a darker center), the nucleus surrounded by a space of lighter gray between it and the darker wall. With suspended accommodation these cells, as shown against a cloud, seem to subtend an angle of perhaps one or two minutes, and all outlines are softened or blurred. With the accommodation active, these cells, with their (four-fifths or nine-tenths?) reduction in size, gain definiteness of contour and structure, and what seemed before as discrete cells are usually found to be arranged in chains or necklaces, the cells often marking an angle or curving-point from which extends an indistinct and homogeneous band or cord running off to other cells.[1] Almost constantly there are in the field also continuous strings of cells, the intercellular cord seemingly non-existent, and lying in contact with one another. I have counted as many as twenty-five or thirty, or more, "beads" or cells in a single string. Sometimes the strings stretch out almost in a straight line; at other times they are coiled and tangled in a confused mass. They change in appearance every second, as they are moved by the currents of the liquid and motions of the eyeballs. Under the microscope or in illustrations of histologic teased tumor or other tissue, I have seen structures almost exactly like those of certain muscæ vary in their relative density, some falling more rapidly than others. A few seem almost of the same specific gravity as the liquid, and fewer still are lighter. In the same string the beads are almost uniform in size, but are of different sizes in different strands, some being twice the size of others. The larger are usually of indefinite outline and more filmy in appearance, seemingly more swollen and nearer disintegration.

The second class includes mere indeterminate and formless, cloudy or filmy shadows, or shreds of all sizes.

The third class requires for observation extraordinary acuity of vision, long experience and education in ocular ballottement, as well as peculiar and almost indescribable conditions of light. Through a window-slit I have sometimes observed them with remarkable distinctness, upon awakening in the morning, with the retina, of course, in a rested and acutely sensitive condition. They seem like dust or fine rain, settling downward much more slowly after the upward ocular fillip.

As nearly, therefore, as I can observe and classify them, my muscæ are:

1. Cells, or cell-strands, sometimes with intercellular cords, sometimes in juxtaposition, like a close necklace of beads.
2. Formless filmy or cloudy masses.
3. Fine particles, in appearance like soft, fine rain.

I have thus described these aphoses as they appear in a sitting posture, but by lying flat upon one's back and poising them before the macula the second class is soon proved to consist usually of the chains or necklaces that seemed formless only because they were seen by the peripheral portions of the retina, or because matted and massed in a tangle. Such a seemingly formless mass, poised before the macula may even be unraveled or disentangled by numerous ocular ballottements, until all the interlaced and matted strings are washed apart from each other.

Experience and careful observation have convinced me that the quantity of muscægenetic material is vastly greater than has been suspected. Under exceptional circumstances of light, etc., I have certainly observed as many as twenty or thirty separate strands or masses in the field at one time. In my own case I am in perfect health, and the seemingly excessive amount of this material cannot, therefore, be called pathologic. I believe that, in varying degrees, the material is present in every person, requiring only a number of necessary conditions and sufficient attention to make it manifest. While reading, of course, the lateral motions of the eyes do not make this vastly larger part of particles surge upward into the field of view, either to obscure vision or to become noticeable, and when walking they are not observable by anyone. If the motion of the eyes in reading were up and down, they would certainly be more troublesome. While still physiologic the amount of matter is never so great as dis-

[1] It was this, I think, that v. Zehender saw in his experiment, and not a reflex of the optic nerve.

tinctly to cloud vision, except in microscopic work or in such climatic surroundings as are fitted to bring it before the attention. Then it must not be forgotten that only as it rises into or descends through the small space lighted by the pupil is it possible for the retina to note its existence. There is doubtless, all about, a cavity or peripheral portion of the aqueovitreous chamber large in extent as compared with the area illuminated through the pupil, because by ballottement the muscæ fall out of sight and rise again out of an unseen space. Moreover, the peripheral muscæ at one time in the field never occupy what I should judge to be over 40° or 50° of the extramacular field. Even within this space, however, the trained and sensitive retina directed to the zenith perceives a vastly larger amount of muscæ-genetic material than would have been believed possible. It may also be noted that out of doors, or in well-lit rooms, the pupil is contracted, whilst in mydriasis the conditions of observation and study are destroyed.

There is a toy that crudely but strikingly illustrates the manifest fact. It is a hollow glass globe, filled with fluid, at the base of which are illustrated a house, people, etc. The fluid contains a sort of sand, of slightly heavier specific gravity than the liquid. By shaking the white sand a mimic "snow-storm" is produced as the grains settle to the bottom. If this globe were surrounded with black paper, except at one point, leaving an imitation pupil, and at the opposite end a hole to look into, and if into the liquid were thrown diaphanous or translucent shreds of teased and broken-down tissue in all states of degeneration, by manipulations, or "ballottements," one would have all the essential phenomena of the eye described, providing the size and refraction of the globe were such as to create the verisimilitude. The "chamber" of the eye, instead of being round and roomy as in the toy, is but a thin vertical space, between the vitreous and the structures in front of it, possibly thinner in the center, and deepening at the periphery adjacent to the ligament of the lens. Never have I seen a strand of cells as if "end-on," and rarely more than one or two behind another. In the region pierced by the visual axis, the chamber is therefore not much deeper than two or three times the thickness of the lining membrane of a vitreous cell.

The Function of the Aqueovitreous Chamber and its Contents. What an organ does, that is its function—and its functions, as those of most structures, are often multiple and made to serve multiple purposes. It is the fault of physicians that, having discovered one use of an organ, or one factor in the etiology of disease, they rest content and do not learn that, generally, disease has more than one, often several causes. In physiology, *e. g.*, the object of winking has always been given as the cleansing and the keeping of the cornea uniformly moist. Doubtless a result as absolutely important is that of giving the retina temporary rests of darkness, whereby the extremely complex and unstable sensitiveness (visual purple or what not) is re-established. One may doubt if there is a more difficult and enormously delicate labor carried on by the animal economy than that of first making and then keeping the retina in that receptively delicate condition necessary for response to the inconceivably and infinitesimally slight stimulus of light. Muscæ may be considered as one such aid in securing an instant's rest, in temporarily shading, and continuously replacing light by shade, upon which the retinal equilibrium depends. Thousands of times every day these shadowy particles, ever variant in size and qualities, glide unnoticed in front of the macular region, and together with winking give it an instant's reduction or relaxation from the strain of visual response. But other and more important functions are suggested.

1. The existence of such a chamber serves to unravel the mystery of, at least, one aspect of vitreous nutrition, disconnected, as the vitreous body so largely is, from the usual means of excreting waste products. The hyaloid canal aids lymphatic excretion through the optic nerve, but both it and the hyaloid membrane are open in front and permit drainage into the aqueovitreous chamber there located. Into this space are extruded the products of tissue-metamorphosis, the collapsed worn-out cells, shreds of tissue—in a word, the débris of vitreous katabolic change.

2. The liquid may have a useful purpose as a lubricant and buffer in the ceaseless changes and frictions of the mechanism of accommodation, in equalizing and distributing pressure, etc. If the vitreous were pressed close against the filtering membrane, the passage of any liquid through the septum into the aqueous chamber would be greatly impeded.

3. Possibly more important still, the chamber may have a most useful and necessary function as a "settling-basin," wherein the undissolved products of vitreous excretion are shoved, and thus gotten out of the way of direct vision so far as relates to *fixed* and *continuous* opacifications. What a nuisance it would be to have a single musca cell permanently before the macula!

4. As is well known, the liquid of the first exhaustion of the aqueous chamber is non-albuminous and non coagulable. Upon the reformation of the aqueous a second tapping is found to yield an albuminous and coagulable fluid. The significance of this fact in wounds of the cornea is evident. May the aqueovitreous chamber not aid in this function and serve as a storehouse or reserve stock for re-

filling the aqueous chamber, and in case of traumatism, with a readily coagulable fluid?

5. Doubtless by far the most important use, however, is that of attrition, dissolution, breaking-down, and liquefaction of the débris of vitreous excretion, so that this may pass into the absorbent channels and thus finally be disposed of. The process to which these particles are subjected by the ceaseless motions of the eyes is a genuine churning-process, the narrowness of the space in which they are confined rendering it all the more effective in the uninterrupted friction of the particles against each other and against the boundaries of the chamber. It may also be possible that the liquid may have some true digestive power to hasten the process of liquefaction. Active out-of-door life begets healthier eyes than indoor life, and to some extent this may be due to the more effective nutrition resulting from better local conditions of attrition, etc., in the "churning-process," resulting from bodily and ocular motility.

6. The translucent muscægenetic particles floating in the chamber may afford the incidental shading of all parts of the macular region to which allusion has been made, and thus serve to give slight relief from the constant glare of light that, as all know, is so harmful to retinal sensitiveness. In this respect they serve to supplement the act of winking, as every wink slightly stirs the sediment of the liquid, just as to a greater extent does every contraction of the extra-ocular muscles, incessantly active during waking.

The query arises and may be worth noting parenthetically, whether the products of this dissolution-process or digestion may not in some way be utilized by the lens as nutritive material. So large an amount of organic matter, half or wholly digested and lying in constant contact with the capsules and ligaments of that organ, the only supply of nutriment of which is drawn from this cavity, must certainly exercise an important influence upon its nutritional condition and repair. But this aspect leads me to remark upon a possibly pathologic significance growing out of the ensemble of facts and inferences that have been set forth.

The two most common, most mysterious, most serious, and, to treatment, most intractable, of all diseases of the eye are cataract and glaucoma. The etiology of each is as obscure as the treatment is unsatisfactory. That the best minds of a special class of brilliantly intellectual medical men have failed so far to bring solutions to these questions makes me shrink from any but the most modest suggestion of a not improbable explanation.

A Possible Factor in the Etiology of Cataract. Whether or not the lens and its capsules, for purposes of nutrition, make any physiologic use of the dissolved and digested organic matter bathing the posterior capsule and ligament, it does not seem otherwise than reasonable that with pathologic conditions of this liquid there may ensue pathologic conditions of the lens and disturbances of its nutrition. Careful consideration of the influences and circumstances at work, of the transcendent delicacy of the processes, and of the instability of the equilibrium or balance between secretion and excretion of the "closed system" of the eye—all these and other things that might be enumerated make it plain that pathologic states of the liquid of the aqueovitreous chamber may readily arise. When one reflects upon the unsuspectedly large amount of normal undissolved muscægenetic material or débris of this chamber, it is readily seen that a slight increase in the amount above the normal would readily change physiology into pathology. Under such circumstances digestion would quickly become dyspepsia—and especially so in the already deteriorated nutritional processes of the aged, of the weak, etc. Then, also, it should be remembered that the slightest decrease of the amount of the diluent, the secretion filling the chamber, would have the same effect. Let one also realize well the necessarily small capacity of the chamber, the general microscopic plan of the space, the parts and processes, and it will become plain that the narrow line separating physiology and pathology is most easily passed. Senile cataract does not arise until the late period of life when nutritional disturbances are at work in the entire organism and the lessened vital forces are more and more incapable of repairing the ravages of tissue-waste and injury. I have myself no doubt that long-continued uncorrected eye-strain is a potent factor in the production of senile cataract, but that it acts alone, without other contributing agencies, is hardly supposable. With the growing inelasticity of the lens—presbyopia—(may this inelasticity itself not depend upon local (muscal?) as well as systemic denutrition?) the presbyopic ciliary muscle does not cease to work—indeed, its labors are perhaps all the more straining and irritating. Uncorrected astigmatism in presbyopes thus serves to induce pathologic conditions of the ligament and capsule of the lens (the filtering membrane), with irritation and denutrition. I would only hazard the suggestion that a morbid condition of the fluid bathing the parts, an excess of undigested muscæ, a slight upsetting of the balance between secretion and excretion, may cooperate with ametropia and systemic denutrition to produce the local lenticular denutrition or morbidity called cataract.[1]

[1] Certain forms of anterior choroiditis, cyclitis, "posterior capsulitis," etc., may possibly be caused or complicated by such conditions. Bacteria introduced through traumatism or other means would find here a culture-medium well adapted for their multiplication.

The Etiology of Glaucoma. The obliteration of the filtration-angle is beyond question the immediate or secondary cause of glaucoma, but what is the *causa causæ*—the cause of the cause? Why the increased pressure from behind? To this question no answer has been given. Closure of the filtration-angle or of the canal of Schlemm, and excessive secretion in the vitreous chamber—deficient excretion in front, and over-production behind—have seemed the sole alternatives. To these I would add a third, the choking or clogging of the sieve, the membranous septum of the lens-ligament, by the débris-sediment, or solution of the aqueovitreous chamber. Excreted organic matter, softened, partially liquefied, or partially digested, granular, or viscid, of all possible substances, would be most perfectly adapted to choke up the pores and the intercellular spaces of a membranous diaphragm. This is so outside of the body in the osmotic processes of dead membranes, and it cannot fail to occur in the living membrane.

It may be urged that such a choking of the septum would at best only be likely at the bottom of the chamber, where the sedimental particles naturally settle. The objection ignores three facts:

1. It is not at all to be taken for granted that only it is the visible, the heavier, or the larger particles that may choke the membrane the most. It may possibly be the lighter and finer, the more dissolved varieties that are not seen at all, or that are rarely seen; or, still more probable, the liquid itself, made over-viscid by too much dissolved material.

2. We do not know but that the top of the chamber may be equally or even more charged with non-liquefied, unabsorbed material of lighter specific gravity than the liquid. This would seem very plausible. Such particles would not often produce muscæ, because, to reason from analogy with objective solutions, such floating matter would, by the motions of the eye, not be submerged, and thus be brought into the area to render them visible. That some muscægenetic particles are lighter than the liquid, and do inhabit the upper part of the chamber, I have (rarely) proved.

3. Most significant still is the answer that we forget that one-third of our lives is spent in sleep and in lying down. Those who sleep on their sides would expose one of the lateral (when prone, the lowermost) portions of the chamber to impacts of the sedimentation-process, and at a time when immobility of the eyes would permit the injury (if it exist) from sedimentation and choking to be most active. Very few persons lie habitually and continuously all night with the head in one position, so that different parts of the filtering septum are successively exposed for hours to the risk of being covered with an excess of sediment. It is said that in sleep the eyes are turned upward; *i. e.*, as if by contraction of the superior rectus. If so, is it a device of the organism to permit the sediment to drop away from the septum, and at the posterior or flat aspect of the chamber? Sleeping upon the face, or as nearly so as possible, would be the worst position. Certainly upon the back, and without a pillow, would be the single position that would free the septum most from the risk of being covered by sediment. But I have never known but one person who habitually slept in this position. It would be interesting, though by no means conclusive, to learn the position in sleep of glaucomatous patients.

Therapeutics. Not only does this theory of the primary origin of the glaucomatous process seem apriori to meet many or all of the requirements of an explanation, but it also appears to correspond with the clinical demands. All varieties of cases, the acute, fulminant, subacute, or chronic, would be explainable by it as the natural responses of varying degrees, clearings, and modifications of the sedimental chokings of the filtration-septum.

Both cataract and glaucoma occur in those over forty or fifty years of age, when diminution of secretion and lessening of the general nutritive processes are noteworthy characteristics. Diminished secretion of the dissolving or digestive fluid of the aqueovitreous chamber, even to an infinitesmal degree, in the almost infinitesmal proportions of these areas and functions, would at once produce markedly increased viscidity of the contained liquid—a condition also more liable to occur in connection with the corporeal inactivities of old age, as well as the lessened excretory and vital powers of the tissues generally. When this morbidity is, as it were, chronic, only cataract may arise. When it rises to a certain pitch, clogging, or (as workmen say of sieves and drains) "fouling" of the filtering membrane occurs, and we have the glaucomatous process. This heightened process of glaucoma, too, is prone to occur in the nervous, and worried, and anemic, especially in women, in those generally in whom the expenses of the life-process are in excess of the income—*i. e.*, when there is excess of waste product over excretory and secretory repair—specifically, when the aqueovitreous humor tends to become overloaded with semi-dissolved, non-excreted, viscid matter. (Did a fat person ever have glaucoma?) It may be noted, also, that in glaucoma the lens often become cataractous, whether secondarily from pressure or primarily from morbidity of the aqueovitreous humor and denutrition remains to be proved. The increased albuminousness and coagulability of the aqueous humor in glaucoma also tally with what the theory would demand. It is exactly as in the physical process of osmosis under pressure outside of the body. The strange clinical fact that the glaucomatous process is often tem-

porarily checked by sleep should not be forgotten. This has a double significance in the light of the theory here proposed.

When we reach the clinical observations that mydriatics intensify the glaucomatous process, and myotics lessen it, we find that hitherto these facts were purely empiric, and the rationale of the action was hidden. But the myotics, eserin and pilocarpin, increase glandular, osmotic, and secretory activity, while mydriatics correspondingly or to a greater degree lessen them. Now, although an increase in the *amount* of the liquid in the aqueovitreous chamber would seem, apriori, to increase the intraocular pressure; it also would lessen the viscidity of the fluid there, and thus lessen the clogging of the filtration-membrane in front. The reason also becomes clear why this action is the more pronounced the earlier in the glaucomatous process it is instituted, and why it is comparatively resultless in late stages, when the anterior filtration-angle and the canal of Schlemm are occluded by pressure and inflammation, and the results of the glandular functions posteriorly are annulled by the same influences.

Nobody has suggested any satisfactory reason for the empiric fact that iridectomy is of use in a certain class of cases of glaucoma. Sometimes we know it does harm; often it does no good, even in the acute stages, and in the "absolute" or chronic cases, and in glaucoma simplex, it only succeeds in giving any relief in about one-half of the cases. When the tension of the eye is normal it is wholly without effect in reducing tension to subnormality. If the theory I have suggested be proved valid, the explanation of all these facts observed clinically becomes clear, or will become so by investigation. Sclerotomy has undoubtedly effected cure in some cases. But any operative measure, to be effective, must increase the filtration-capacity from the aqueovitreous into the aqueous chamber. A simple hole through the suspensory ligament would undoubtedly be absolutely effective—if we could secure this without producing traumatic cataract or luxation of the lens, and when we can safely extract a non-cataractous lens (in conjunction with posterior discission), we may be able to save some remnant of vision in neglected and otherwise hopelessly ruined glaucomatous eyes. In the light of the theory here set forth, iridectomy can only aid in relieving glaucomatous tension by increasing the porosity of the filtering membrane. Just the precise method in which it effects this I leave for future investigation.

Massage, properly and intelligently applied, would seem to be the most clearly indicated therapeutic measure to break up mechanically the clogging process, stimulate additional secretion of diluting and digestive fluid, and arouse normal function generally.

I have had but one case of glaucoma since groping my way to this theoretic conception of the disease, and that was a typical case, in which vision had been reduced to $\frac{20}{100}$. I began by teaching the patient to some extent the principles, and accurately the manipulations, of massage of the globes of the eyes. There had been no considerable response of the pupil or of the glaucomatous process to eserin. Before proceeding to iridectomy I determined to try massage, and from the day it was instituted improvement began, and the vision steadily rose to $\frac{20}{30}$, with entire cessation of all the symptoms, except that the paralyzed iris still remains somewhat mydriatic and wholly immobile. If the supposed sedimental stasis and choking had not been broken up, stirred up, and helped by means of massage, it would appear that an incision of the sclera beneath the dependent portion of the aqueovitreous chamber, with drainage, and even artificial irrigation of the chamber with a solution of sodium chlorid, would be the natural indication in obstinate and extreme cases.

The foregoing, and especially so far as it relates to cataract and glaucoma, is a study by the method of Zadig, upon a manifestly very small basis of facts. I offer it as a working-hypothesis. I am as well aware as any critic can be of the dangers of extensive inferences from slight data, but all science, in its reachings into the unknown, rests more or less upon Zadig's method, and the only criticism that finally obtains is as to the accuracy of observation of such facts as form the basis of the inquiry, and the inevitableness or firmness of the logical links of the inferential chain. The proof of the whole theory, so far as relates to the last two paragraphs, must finally rest upon the facts of the existence and running away of the Queen's horse itself, its color, its length of tail, its silver shoes, etc.—that is, in our instance, upon the microscopic study of the parts and processes, and upon the result of the therapeutic tests. These things I must leave to others to carry out. If I have erred, and if the suggestions I have offered are either in part or entirely unjustified, my excuse for the haste of publication, prior to experimental provings, is that I would prefer the just censure of the most unsympathetic critic and disprover, rather than to risk the relief of a single patient by withholding what may turn out to be a new ray of light upon the etiology and cure of a group of formidable diseases.

Typhoid-bacilli in the Urine of Typhoid-fever Patients.—WRIGHT and SEMPLE (*Lancet*, No. 3752, p. 196) have reported seven cases of typhoid fever, in six of which typhoid-bacilli were detected in the urine. They consider this evidence as supportive of the view that typhoid fever is a "blood-infection" rather than an "intoxication-process." The practical outcome of these observations is that care should be taken in the disinfection of the urine as well of the intestinal evacuations.

SOME MOOT POINTS IN THE TREATMENT OF APPENDICITIS.[1]

BY MILES F. PORTER, A.M., M.D.,
OF FORT WAYNE, IND.;
PROFESSOR OF SURGERY AND CLINICAL SURGERY AND GYNECOLOGY IN THE FORT WAYNE COLLEGE OF MEDICINE.

I DESIRE to premise this paper by saying that it is based very largely on the literature of the subject. My own experience has not been sufficient to allow me to give any great weight to deductions drawn from it alone.

Briefly stated, I have had under my care within the past seven years fifteen cases of appendicitis. Eight were pus-cases, seven of which were treated by incision and drainage and one by removal of the appendix. One case was drained through the healthy peritoneal cavity. In the other six cases the peritoneal cavity was not opened.

Seven cases were treated without operation. All recovered. There has been no relapse and no permanent fistula. Two of the cases are too recent to determine as to the permanency of the cures.

While I believe appendicitis to be from start to finish a surgical disease—*i. e.*, one demanding the services of a surgeon—I cannot subscribe to the doctrine that all cases require operation. My experience, together with a careful study of the subject, compels me to believe that by the exercise of good surgical judgment a large number of cases will be found in which non-operative treatment will yield the best results. In a previous paper[2] seventy-seven cases were tabulated in which operation was not deemed advisable; all recovered without recurrence so far as known, though all of them could not be followed. To these I can now add two more occurring in my own practice. Richardson, of Boston, also reports[3] fifty cases treated medically, without a death.

When there is pus, perforation, or severe peritonitis, operation is demanded; as it is also in those cases in which there is imminent danger of those conditions arising. Of course, I am aware that many hold that no man can tell when a mild case will develop into a severe one, which an operation cannot save. I believe this to be possible, but contend that it is a rare exception. In this connection we must not reckon without those fulminant cases in which fatal conditions obtain in a few hours, and in which death results, no matter how prompt the operative interference. In these cases fatal sepsis, peritonitis, or other fatal conditions are present when the symptoms first manifest themselves. In my paper already referred to are tabulated fourteen primary cases in which there was suppuration or perforation almost from the beginning.

[1] Read at the meeting of the Madison County Medical Society, Alexandria, Ind., July 2, 1895.
[2] American Journal of the Medical Sciences, December, 1893.
[3] American Journal of the Medical Sciences, January, 1895.

Chronic cases, and cases in which recurrences are frequent, should, in my judgment, be subjected to operation, for the risk of operation in those cases is no greater than one would be willing to take for the chance he would have of permanent and complete recovery.

Before this question can be definitely settled, it seems to me necessary to collect a large number of cases from the practice of those who operate in all cases as soon as the diagnosis can be made and wherein they have had the opportunity of making early diagnoses, and an equally large number of cases treated under similar conditions by those who take the position that some cases require operation and others do not. As yet the statistics for such comparison are not adequate.

In case of operation there can be no question that the appendix should be removed in cases without pus, cases of endo-appendiceal abscess, and in the majority of peri-appendiceal abscesses in which it is necessary to carry the drainage through the general peritoneal cavity; also in cases of gangrene or perforation without limiting adhesions.

Exception should be made in favor of rapid opening, cleansing, and drainage, preferably with gauze, in cases of this latter class operated upon *in extremis*. In this class of cases prolonged operation means death, and the surgeon should sacrifice the ideal for the sake of the life in his hands, albeit he may but rarely succeed in saving it.

Concerning those cases in which there is a circumscribed collection of pus that can be opened without entering the general cavity of the peritoneum there is much difference of opinion. Maurice Richardson says:[1] "If, for no other reason, the low mortality in cases of circumscribed abscess, and the perfectly satisfactory and permanent results that have followed simple incision and drainage, are sufficient grounds for limiting our operations to the cavity itself." He has had but two recurrences after drainage, and in one of these the drainage was through the rectum. That appendisectomy is attended with infinitely greater primary danger than simple drainage in these cases cannot, of course, be denied. One need only to read the reported cases to be convinced that, already, lives that might have been saved by simple incision and drainage have been sacrificed through adherence to the dogma that the appendix should always be removed. To offset this greater danger there should be unquestionable proof that the removal of the appendix offers security against recurrence or other dangers that, though perhaps not so immediate, are still none the less real. The cases thus far reported fail to furnish this proof.

Cases of recurrence of abscess are not unknown

[1] Loc. cit.

by any means after the so-called "ideal" operation. In a case reported by Richardson,[1] operated upon by Dr. Beach, who removed the appendix, the patient subsequently developed an abscess, which was opened and drained, and a week later was seized with sudden and violent abdominal pains, and died.

Dr. Fowler,[2] of New York, also reports a case in which an abscess developed three months after an appendisectomy.

Dr. Richardson[3] reports recurrence of all symptoms of appendicitis a year after a removal effected by him, but in which the symptoms subsided without further operative interference. A. C. Bernays, in a letter to me, reports a case in which after removal of the appendix there were two relapses, death following the operation in the second relapse. Other cases of similar kind might be cited, but the foregoing are sufficient to show that appendisectomy does not render patients upon whom it is performed absolutely immune from further trouble in the right iliac region.

Theoretically there would be, it seems at first sight, great advantage in removing the appendix, inasmuch as the ligature shuts off communication between the abscess-cavity and the bowel; while in removing the appendix we remove the origin of the trouble. Practically, however, in a great many cases this communication between the bowel and the abscess has already been closed by inflammatory processes; while the appendix itself is only one among many equally potent sources of infection. The abscess-walls are infiltrated with germs and the coats of the bowel are softened, and through them infection is constantly being added. Removal of the appendix does not remove these sources of infection, while the tearing of the adhesions and the manipulations necessary to removal of the appendix liberate these germs from the abscess-walls, inhibit the power of resistance of the tissues, and increase the transmigration of the germs from the bowel. In my paper already referred to I say: "The complete and permanent recovery of the patient after removal of the appendix in no small measure depends upon the treatment of the stump. The ideal method seems to be that in which the stump, after ligation, is turned into the cecum and buried by Lembert sutures as described by Senn,[4] and described and illustrated by Morris in the *New England Medical Monthly*, April, 1893, p. 331. Indeed, I am convinced by a careful study of all the literature upon this point accessible to me that, unless the stump be thus treated or in some way be covered by peritoneum after ligation, the removal of the appendix leaves the patient in great danger of perforation." I am still of the opinion that this ground is well taken. This treatment of the stump is not practicable in the class of cases under discussion; hence, in them fecal fistulæ are but little if any more uncommon after appendisectomy than after incision and drainage.[1]

By removing the appendix we unquestionably remove one source of infection, and therefore it should be removed if it can be done without additional risk. However, in the majority of cases of the class now under discussion the advantages over incision and drainage that removal of the appendix offers are more than counterbalanced by the risks that it adds.

Another objection to too close adherence to the "ideal" operation is that it must inevitably lead to unnecessary operations. Not every collection of pus in the right iliac region, even in males, has its origin in the appendix. I saw a case at Defiance, Ohio, in consultation with Dr. Thatcher, in which a diagnosis of appendicitis with abscess had been made. I concurred in the diagnosis, but the man refused operation. He died in a few days, and an autopsy showed the appendix healthy, the pus being due to ulceration of the cecum. Rushmore[2] reports a similar case. Murphy[3] reports a case of total destruction of the mucous membrane of the colon, with a large abscess.

I think we are warranted in concluding as follows:

1. All cases of appendicitis do not require operation; on the contrary, some cases are best treated without operation.

2. In cases requiring operation the appendix should be removed: (*a*) when there is no pus; (*b*) when an endo-appendiceal abscess is present; (*c*) as a rule, when there is a peri-appendiceal abscess that requires drainage through the general peritoneal cavity; and (*d*) when there is general peritonitis without adhesions, with the exception noted.

3. A simple incision should be made and drainage provided in cases with circumscribed abscess, when this can be done without opening the healthy peritoneal cavity. An exception should be made to this rule in cases in which the removal of the appendix will not add to the gravity of the operation.

47 WEST WAYNE STREET.

Dr. James Ash, of Philadelphia, died of pneumonia at Asbury Park, N. J., on September 2d, at the age of seventy-seven years.

CHRONIC GONORRHEA AND MARRIAGE.

BY FRANK P. VALE,
OF WASHINGTON, D. C.

IN looking over this subject one finds very little to guide him in giving advice to chronic blennorrhagics who wish to marry. There is ample evidence, however, of the danger of infecting the wife under such circumstances. Nearly a quarter of a century ago Noeggerath called attention to the important part played by chronic or latent gonorrhea as a cause of pelvic troubles in the female, and, although adversely criticised at the time, his views are now regarded as being in the main correct. It is well established that long after apparent cure men may infect their wives. The infection does not always manifest itself as an acute vulvovaginitis. The first symptoms complained of may be due to a metritis, which has developed slowly and insidiously, the inflammatory process extending finally to the tubes and ovaries.

The rules laid down by Finger with regard to chronic gonorrhea and marriage are generally accepted. Janet, however, regards them as being in some respects superfluous, and in others as not sufficiently strict and rigorous. An interesting case, bearing upon this subject, is reported by Brewer.[1] He was consulted by a gentleman contemplating marriage, who had had an obstinate attack of gonorrhea six years before, but who had been free from symptoms for the last three years, with the exception of occasional slight moisture at the meatus. Examination of his urine showed shreds in which gonococci were found. He married, contrary to advice, and two weeks after the ceremony his wife developed an acute gonorrhea.

Brewer accepts Finger's rules, viz.: that daily examination of the shreds in the urine for three weeks show neither gonococci nor pus-cells; that a purulent discharge caused by irrigation of the urethra with a solution of mercuric chlorid or of silver nitrate show no gonococci; that there be neither stricture nor prostatitis. Brewer's own rule had previously been to wait until three months after the subsidence of all acute symptoms, examination of the shreds not showing the presence of any gonococci. Finger lays especial stress on the requirement that pus-cells should be absent from the shreds, adding that after long and laborious examinations with negative results the gonococci may suddenly appear. He most urgently cautions against depending on ordinary bacteriologic examinations, and does not allow marriage until pus-corpuscles are absent from the shreds. A case that is still under my care has impressed upon me the value of this advice, and more particularly the necessity of avoiding the conclusion that gonococci are absent until certain therapeutic reactions, which are especially advised by Janet, have been employed, and the secretions of the resulting recrudescence carefully and repeatedly examined.

Mr. A. was sent to me July 8, 1895. Three months before he had contracted gonorrhea. He was to be married in the latter part of August. From the examination of his urine and the history of his case, I concluded that the inflammation had extended posteriorly. After the first jet the urine was uniformly cloudy. Examination of the shreds showed no gonococci. There was a slight succulent narrowing about the middle of the penile urethra. For three weeks I daily passed the largest sound his incised meatus would admit, practised urethrovesical lavage daily with from 1:5000 to 1:2000 potassium-permanganate solution. After the cloudiness of the urine had disappeared I also made instillations of copper sulphate 1:20, following each permanganate lavage. At the end of three weeks the urine was free from shreds. The next day, Sunday, the patient did not report. On Monday he came with a profuse discharge, which showed typical groups of gonococci in every twenty or thirty cells. The two-glass test showed clear second urine, proving his posterior urethritis to have been cured. I attribute this fortunate recrudescence to the man's having eaten crabs, the only unusual article of his diet on Sunday. It had been fully three months since all acute symptoms had subsided. During three weeks there had been no gonococci, only two or three atypical cocci here and there in the specimens examined. In view of these facts, and with daily washing of the entire urethra with permanganate solutions (supposed to be almost specific against these germs), I am afraid I should have given my consent to his marriage at the appointed time, a course that would undoubtedly have resulted in infection of his wife.

Janet has given us some valuable advice on this subject. He takes exception to the rules of Finger in some respects. He does not think it necessary that leukocytes be absent from the shreds, having seen them in the mucous flakes in the first jet of morning urine in healthy men. They are found, moreover, a long time after a cured gonorrhea. What Janet[1] insists upon, next to the absence of gonococci, is the absence of late secondary infection by diverse organisms, and also of that state of receptivity which predisposes to late secondary infection, and follows as a result of the injury done by the gonococcous invasion.[2] In his latest article[3] Janet revises this opinion somewhat,

[1] Journal of Cutaneous and Genito-Urinary Diseases, March, 1891.

[1] Annales des Maladies des Organes Genito-Urinaires, 1892, pp. 275 et seq.

[2] Ibid., 1893.

[3] Ibid., 1895, pp. 481 et seq.

and instead of forbidding marriage until the urethra has been demonstrated to have recovered from this susceptibility to secondary infection, he allows marriage as soon as the patient is rid of his gonococci and secondary infection, provided the latter agrees to follow instructions given him to prevent late secondary infection.

Janet divides chronic blennorrhagics, with reference to marriage, into two classes: disinfectable and non-disinfectable. With regard to gonococci, he thinks the number of cases in which the patient cannot be freed from his cocci is rendered exceedingly small if permanganate irrigation is practised and if extra-urethral foci be removed when they are found to exist. If the urethral and prostatic glands do not empty themselves they may contain such foci. Under these conditions, massage and expression of the prostate and urethra immediately after micturition will bring to the meatus the retained secretions of these glands, in which gonococci will be found. Disinfection of these foci is accomplished by thus emptying the glands before each lavage. Ordinarily these glands empty themselves and are not without the sphere of disinfection by the permanganate irrigation. Of course, there may be cases, as in infection of the vesiculæ seminales, in which it may be difficult or impossible to remove all foci.[1]

Without underrating the importance of miscarriages and the sequelæ of confinements as causes of metritis and salpingitis in young married women, and considering the enormous number of such cases, and the large number in which gonococci cannot be found in the husband, the question of secondary infection becomes of capital significance. In non-disinfectable cases in which secondary infection by diverse organisms has extended to the prostate, bladder, and possibly even to the kidneys, marriage should be prohibited just as much as in cases of uncured syphilis. In those cases in which secondary infection has been cured by immediate and proper treatment by irrigation with a solution of mercuric chlorid, the urethra is for months abnormally susceptible to invasion by diverse organisms normally present in the vagina. These organisms, after gaining vigor in the new soil of the male urethra, are capable of infecting the woman, especially at certain times when she is unusually susceptible, as after confinement and miscarriage. Therefore, if a patient marries whose urethra is entirely rid of all organisms, but in whom this abnormal receptivity still exists, he should take certain precautions to avoid infecting his wife. After each coitus he must prevent infection of his urethra by disinfecting his meatus with a solution of 1 : 1000 mercuric chlorid. Moreover, if a drop of secretion appears at the meatus at any time he must cease conjugal relations until a bacterioscopic examination has been made, and, if necessary, his urethra should again be disinfected.

Janet is of opinion that these recrudescences from late secondary infections are what give rise to the quite widespread belief that gonorrhea is never cured. The matter of demonstrating the absence of gonococci and other organisms is very important. If cocci are not found in the discharge or shreds, it is not to be concluded that they are absent. A recrudescence can be induced by irrigating the anterior urethra with 1 : 20,000 solution of mercuric chlorid or a 1 : 1000 solution of silver nitrate, or, what Janet believes is just as efficacious, if gonococci are present, by having the patient drink beer. If, after repeated examinations, no gonococci are found in the purulent discharge thus induced, the glands of the prostate and urethra should be expressed, and, if these contain any foci, the retained secretions will be forced out and brought to the meatus. Furthermore, in looking for other organisms, the urine should be examined for any cloudiness of the second part which does not clear up on heating or the addition of acetic acid. If the bladder is infected, the organisms will be numerous in the sediment of the second urine. In giving a decision the recognition of gonococci arises. Guiard[1] considers their classic form, site, and arrangement as diagnostic, quoting Steinschneider to the effect that there is a chance of only 1 in 20 of thus mistaking various varieties of diplococci for gonococci. Like the true gonococci these pseudo-gonococci decolorize when stained by Gram's method, but, as shown by Albert Hogge,[2] they decolorize more slowly. Successful cultivation on ordinary media is indicative of pseudo-gonococci, while positive results with the serum of Wertheim and negative results with ordinary media are decisive in favor of true gonococci. It is only by carefully following such suggestions as the foregoing that we can hope to give reliable advice to chronic blennorrhagics who wish to marry. It is certainly preferable to be overcautious than to take the chances of the disastrous consequences that follow ill advice on this very important subject.

The Chair of Pathology in the Faculty of the Jefferson Medical College in Philadelphia is vacant.

[1] According to Alexander (Journal of Cutaneous and Genito-Urinary Diseases, August, 1891), suppurative vesiculitis is exceedingly common, being often mistaken for posterior urethritis. The condition would be recognized in the following manner: The patient having urinated and cleared his urethra, a finger is inserted into the rectum, and, reaching with it above the vesicle, first on one side and then the other, an endeavor is made to milk out its contents. The patient now urinates a second time. If suppurative vesiculitis is present, the urine will contain pus, a little blood, and spermatic fluid.

CLINICAL LECTURE.

CHOREA.

BY CHARLES CARY, M.D.,
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, UNIVERSITY OF BUFFALO.

[Clinical lecture delivered at the Buffalo General Hospital.]

THIS child is ten years old, with nothing significant in the family history. She has had scarlet fever and measles. Two years ago she was treated in the hospital for malnutrition, and also received attention from Dr. Putnam on account of some nervous trouble. After remaining in the hospital for five or six months the child went away, improved. Last November she was again received into the hospital on account of rheumatism, complicated with what, for the present, we may call twitchings, and recovered after a month. On February 26th she re-entered with the same nervous phenomena, which had returned about Christmas. There was also noticed at the time of the first examination a heart-murmur, and the girl was very anemic. The child, as you have observed, answers my questions intelligently, corroborates the information given in the history and informs me that she has St. Vitus' dance. She says that she has no pain, but that she cannot stand still. By force of will, however, she can keep still for a minute, but the movements seem more irregular after this effort. Her gait is peculiar and shows a certain lack of muscular control.

Usually, the twitchings of this disease are seen in the face, especially in children at the critical age of puberty. I remember a companion of mine in boyhood who would make a peculiar contraction of the face and mouth that led us to give him the name of "the fly-catcher." Often the earliest manifestation of the disease consists in certain uneasy movements, which lead to reprimands at school or at home for awkwardness, or what is supposed to be unruly conduct. Children are often made worse by being ridiculed and scolded for these nervous phenomena, which are not recognized as constituting a disease.

This child has a mild form of the disease. She can pick up a pin without much trouble and she can control the movements temporarily, a fact that is characteristic of mild forms of the disease and that enables us, in some cases, to distinguish it from other forms attended with tremor or spasmodic movements. If she had St. Vitus' dance in a severe degree, she would find it impossible to pick up a pin, especially when making a conscious effort in the presence of such an audience as this, and she would be unable to control the movements even temporarily. As the patient is stripped to the waist you will notice a twitching of the arms and shoulders. These movements cease during sleep, even in the worst grades of chorea, though the disease may be so severe as to make sleep almost impossible.

The disease is most likely to attack children who are ill nourished, though it does not always spare those of the wealthier classes. It is also interesting to note that the disease occurs in connection with rheumatism, as in the present example. The essential cause of the disease is not known, but it seems to be a disturbance of the central motor powers. On account of the frequency with which somewhat similar symptoms are found to be due to small emboli, the same cause has been assigned for chorea; but this view has not been substantiated by autopsies, though we do not, as a rule, expect choreic patients to die. Last fall the child had an attack of rheumatism, beginning in October and lasting well through November. The feet and legs were swollen and the knees were red and painful, so that the girl was confined to bed for a week before she came to the hospital. On careful questioning I learn that she had these motor symptoms at that time too. I believe it is an open question whether the chorea was due to rheumatism, or whether what was here and has been in other instances called rheumatism is really a general infection due to the choreic disease. We are gradually coming to the belief that chorea is an infectious disease, or, at least, due to some indirect infection. It is not limited to the human race, but occurs also in dogs after distemper and, perhaps, occurs in other animals. In this case, as often happens, a heart-murmur was discovered. Such murmurs have been considered merely anemic; they have also been ascribed to the rheumatism to which the chorea bore simply the relation of a complication; but I believe they represent an essential choreic involvement of the heart-muscle. If we are inclined to the theory that chorea is an infectious disease, we may make a comparison with scarlet fever and gonorrhea, which involve the joints very much as does rheumatism. In all these diseases we must consider the cardiac involvement as analogous to that of the joints, as there is a similarity between the endocardium and the synovial membranes. There is no disease more frequently complicated with endocarditis than chorea—or, perhaps, it would be more accurate to say, there is no other disease consisting so distinctively in part of endocarditis. At present there is no murmur to be detected in this heart, though the first sound is loud and a little prolonged.

Rarely chorea occurs late in pregnancy, and it is then a serious malady, often threatening the life of the woman and necessitating the consideration of the advisability of inducing premature delivery to remove the source of irritation. When I was an interne in the Rochester City Hospital, a young French primigravida was admitted. Barring slight choreic movements, she was perfectly well; but during the several weeks she remained in the hospital the movements increased and her condition became grave. As the time for delivery approached she had to be confined to bed; and, in spite of our efforts to protect her, she would bruise her elbows and knees by the violence of the spasms. She actually wore the skin off from her shoulders and the hair from the back of her head by her constant twitchings and rubbing movements. The last scene was the most interesting. The beginning of labor seemed only to aggravate the choreic movements. I was alone in the hospital, so far as help was concerned, except for the presence of a good, strong nurse, of the old-fashioned type, and we were unable to hold the patient still. In her writhings she threw herself upon the floor, and she and I finally delivered the child on the floor under the bed. She left the hospital after the usual puerperium, quite restored to health.

Chorea usually tends to perfect recovery, but it is likely to recur once or twice in the course of the first year or two after the primary attack. This child suffered from chorea two years ago and has returned to us after

an attack in the interim of what was called rheumatism, but which was accompanied by twitchings, and which was, probably, choreic in its nature. Fatal cases rarely occur, but the disease is serious when it occurs in children already suffering from malnutrition and when it attacks a pregnant woman.

A hospital is not the ideal place in which to treat such a case, but in the present instance, as in too many others, the hospital is far superior to the child's home-surroundings. The treatment should be largely of a hygienic nature and the patient should be out of doors as much as possible. The child must not only be allowed an abundance of pure air, but it should be permitted a perfect freedom and should enjoy itself as much as possible. Unless the patient is more than usually susceptible to ridicule it should play with its companions and be encouraged to have outdoor enjoyment. Still it must be remembered that nervous children are likely to acquire a similar twitching, not through infection, but through imitation. The only medicine that seems to do any good, so far as the permanent relief of the affection is concerned, is arsenic. This acts by improving the nervous tone, though in what way we do not know. Iron should be combined with the arsenic when there is anemia. The usual way of administering arsenic is in the form of Fowler's solution of potassium arsenite, beginning with three drops three times a day and running up, drop by drop, to the full degree of tolerance, as indicated by a slight puffiness under the eyes, and, perhaps, by slight colicky pains and looseness of the bowels. If the muscular movements are extreme, the main dependence is upon potassium bromid. If sleep is interfered with by the choreic movements, chloral may be given, though this drug must always be administered with caution. Cimicifuga has had a great reputation, but I have never been sufficiently convinced of its value to try it. Electricity has also been recommended, but I have very little faith in this remedy. Bathing is often of value, and various symptoms may call for special consideration.

CLINICAL MEMORANDUM.

REPORT OF A CASE OF ADDISON'S DISEASE, WITH REMARKS.

By H. W. McLAUTHLIN, M D.,

OF DENVER, COLO.;

PROFESSOR OF MEDICINE IN THE UNIVERSITY OF COLORADO, VISITING PHYSICIAN TO THE ARAPAHOE COUNTY AND TO ST. LUKE'S HOSPITALS.

MISS ELIZABETH H., aged forty-seven years, white, a native of Ireland, resident of Canada before coming to Colorado, engaged in housework, was admitted to the Arapahoe County Hospital on May 31, 1894, in the service of Dr. Henry Sewall. The following history, taken at the time, is prepared from the hospital-records: The family history was negative. The patient was always well till the age of twenty years, when she was sick about three weeks with so-called congestion of the lungs. In 1889, when forty years old, she first noticed a discoloration on the forehead, which gradually deepened and spread over the body. She was confined to bed all of that summer, (probably from weakness, although the history does not state). She suffered from constipation and pain in the lower part of the back. From that time she had been up and down all the time. The least exertion caused great prostration, with pain in the back and sides. The face presented a uniform, dark discoloration, with areas of much deeper brown. The color was particularly dark and uniform over the neck, forearms, and backs of the hands. On the body and lower limbs the color was lighter, but deepened again on the abdomen, over the backs of the hips, and the inside of the thighs. The tongue was streaked with dark pigment, especially on the edges, as if the patient had eaten blackberries. She complained of tenderness over the left chest and the abdomen. Nothing abnormal was discovered in the lungs. The heart-sounds were weak, but otherwise normal. The abdomen was flat, with marked aortic pulsation. The lumbar curve of the spine was increased. The urine showed a specific gravity of 1012; the reaction was alkaline; but the fluid contained no albumin or sugar. After remaining in the hospital five-and-a-half months the woman was discharged on November 14, 1894, from the service of Dr. Fisk, the record bearing the inscription "no change in condition."

During her stay in the hospital the pulse varied between 76 and 98, averaging about 84, the respirations averaging about 21. The temperature-chart showed an evening rise of from one-half to one-and-a-half degrees during a considerable portion of the time. The bowels were constipated, with occasional attacks of diarrhea. The patient was readmitted to my own service on March 24, 1895. She was then completely bedridden, while anorexia and vomiting were prominent symptoms. She was extremely weak and much emaciated. The heart-sounds and pulse were very feeble. The pigmentation had deepened, especially in small spots over the body, and it was particularly marked on the tongue. The urine was slightly alkaline, otherwise normal. The pulse was 94. In the epigastric region there was a circular area yielding dulness on deep percussion and hard and immovable on palpation. This was thought to be connected with the spine. The woman sank steadily and died April 9, 1895.

Two days later Dr. Leonard Freeman, pathologist to the hospital, performed the postmortem examination. The body was that of an emaciated white woman, between fifty-five and sixty years of age apparently, presenting marked postmortem rigidity and staining. The skin of the entire body was markedly bronzed, more especially about the hands, arms, neck, face, and tongue. The tongue was quite dark in color, while the mucous membrane of the mouth was but slightly altered, excepting for a bluish discoloration along the gums. There were a number of small dark-brown spots, like freckles, scattered over the face and body. The subcutaneous fat was unusually yellow and over the abdomen was from one-and-one-quarter to one-and-one-half inches thick, notwithstanding the general emaciation. Owing to a marked bending forward of the vertebral column a hard projection within the abdominal cavity could be felt externally. The right lung was universally bound by old adhesions, especially at the apex, where there was a nodular mass of tuberculous material, caseous and fibrous in character. The bronchial glands were enlarged and tuberculous. The left lung was also tuberculous. The heart was small and flabby, with dilated vessels, the valves negative and free from atheroma. The walls of the left ventricle were thin, while the heart-muscle was

firm and very brown in color. The left suprarenal capsule was much atrophied. There was a caseous, slightly calcareous, tuberculous nodule, the size of a hazelnut, at the internal and superior angle of the capsule; also a second small caseous nodule, the size of a pin's head. Around these nodules there was considerable fibrous thickening of the adjacent tissue, making a deposit adherent to the spine. The right suprarenal capsule was also considerably atrophied and presented two caseated nodules, each about the size of a grain of corn. The left kidney was surrounded by considerable fat and was slightly smaller than normal, while the capsule was somewhat adherent, leaving on removal a finely granular surface. The cortex was about one-fourth the usual thickness. The entire kidney was congested and in a condition of chronic interstitial inflammation. The right kidney was similar, but had more extensive adhesions of the capsule. There was no thickening of the nerves, or tumors of any kind, to be felt in the region corresponding to the suprarenal capsule. The spleen was slightly enlarged, but otherwise normal. The liver was one-fourth smaller than normal, the edges slightly rounded. Its tissue did not cut readily, and was considerably firmer than normal, while the color was darker. The gall-bladder and the bile-ducts presented no evident obstruction. The lower few feet of the small intestine were negative. The uterus was small; the ovaries and tubes negative.

Addison first described, in 1855, the disease that bears his name. He gave as the general symptoms, anemia, general weakness, especially a weak heart, together with irritability of the stomach and a discoloration of the skin. These have remained the principal symptoms, except that anemia is no longer prominently placed in the list. That the disease is rare in America is shown from the fact that Osler, in 1892, had seen only eight cases, including his work at the bedside and the post-mortem table.

Males are about twice as frequently affected as females. The age is that of young adults, or from twenty to forty years. One congenital case has been described.

In a majority of cases tuberculosis of the suprarenal capsules, and often of other parts of the body, especially the lungs, is present. In such cases the capsules are thickened and contain cheesy masses encased in thick fibrous tissue. Blows on the abdomen or over the kidneys and caries of the spine have so frequently preceded the beginning of the morbid process in the capsules as to merit an etiologic relationship.

Other pathologic conditions of the capsules sometimes found are atrophy from interstitial cirrhosis and malignant disease. The fibrous thickening that encases the capsules usually extends so as to involve adjacent nerves and ganglia of the abdominal sympathetic system, causing their compression and atrophy.

Based upon the pathologic changes mentioned, two theories are advanced to explain the characteristic symptoms of this disease: First, that, owing to the function of the adrenals being lost, the system is poisoned by the retention and circulation of some unknown substance that the adrenals should have eliminated or altered; second, that the symptoms are due to a disease of the abdominal sympathetic system, which is caused generally by disease of the adrenals, but which may also be caused by other chronic diseases involving the solar plexus and its nerves. In support of this theory is mentioned the pigmentation of the skin seen in tuberculous peritonitis, carcinoma of the pancreas, abdominal aneurism, and so on. It seems highly probable, however, that without the adrenal disease the complete group of symptoms characteristic of Addison's sickness is never found. Both of the foregoing explanations may be correct, and both may be concerned in the production of the disease.

The first symptom to attract attention is generally the pigmentation of the skin. This varies from a light brown or smoke-color to black. It is diffuse, but is distinctly more marked on the exposed parts of the body, and where pigment is naturally present. As in the case reported, there may be small isolated spots that are distinctly darker. The face and the backs of the hands are early affected. The mucous membrane of the conjunctivæ, mouth, and vagina is pigmented. Even the serous membranes may be discolored in patches. On the other hand, an occasional case, which is otherwise typical, may show no pigmentation. Such a case is reported[1] by Dr. Warren Coleman, of New York. Adrenal disease was not suspected during life.

The patient was a Danish sailor, thirty-six years of age, who entered Bellevue Hospital on account of constipation. Death took place about three weeks later, without any assignable cause. During his stay in the hospital the man attracted attention only as a case of obstinate constipation, with marked inanition. No interpreter could be found, so the history was not obtained. There was marked asthenia without apparent cause. The temperature was at no time over 101°. The heart's action was feeble and the superficial circulation was poor. The constipation continued, in spite of vigorous treatment, up to the time of death. There is no record of alternating diarrhea.

At the autopsy the body was found anemic, but not much emaciated. The heart weighed nine ounces, and its walls were pale. The valves were normal. The right lung was bound to the chest-wall by a few old adhesions. The upper lobe contained several tuberculous masses of considerable size in a state of caseation, while throughout the middle and lower lobes a few small nodules were found. The left lung was in a similar condition. The bronchial glands were enlarged and cheesy at the center. The left adrenal body weighed one-and-a-half ounces. Its original shape had been entirely lost. On section it was found to be caseous, and greenish-yellow pus exuded from several points on the cut surface. The cheesy matter had become calcareous at many points. The capsule was much thickened. The right adrenal was one-half the normal size, and weighed one-half ounce. It contained one large and numerous small calcareous masses. Microscopic examination showed the process to be tuberculous. The skin and the mucous membrane of the mouth were carefully examined, but no evidences of discoloration found. No sufficient cause for death, aside from the condition of the adrenals, could be determined. The appearances presented by the adrenals left no doubt that they became infected prior to the lungs or bronchial glands.

Dr. Coleman states that he has systematically examined the adrenal bodies in all the autopsies that he has performed in Bellevue Hospital for two years (the number

[1] Medical Record, November 3, 1894.

is not stated), and this is the first instance in which he has found them tuberculous, although many cases showed extensive tuberculosis in other parts of the body. Unfortunately, in this case the semilunar ganglia and the abdominal sympathetic nerves were not removed for examination. The important deduction from this observation is, that tuberculosis of the adrenals, *per se*, even though both glands be entirely destroyed, is not productive of skin discoloration.

The *Medical Record* of September 9, 1894, contains the report of a case of Dr. Lazarus, of Berlin, in which a child, aged three-and-a-half years, died from a tumor of the left adrenal. The tumor represented one-third of the entire weight of the child, which was thirty-seven pounds. Sarcomatous degeneration of the tumor had begun. During life there was no discoloration of the skin. This case goes to show that malignant tumor of an adrenal may exist without pigmentation of the skin.

In Addison's disease spots of leukoderma, or absence of pigment, are sometimes seen. Gastro-intestinal disturbances, especially nausea, vomiting, and diarrhea, suddenly occurring in persons otherwise habitually constipated, are common. There is a tendency to faint, together with headache, as well as pain in the epigastrium and hypochondria. Over and above all is the marked asthenia, without which the diagnosis is uncertain, for pigmentation may occur in other diseased conditions, especially with abdominal tumors, as tubercles, carcinoma, or lymphoma. It is quite frequently seen with tuberculous peritonitis.

In pregnancy and in uterine disease patches of pigmentation are common.

In disease of the liver, and even in cases of deranged activity of this organ, patches of staining are often seen about the face and forehead. Irritation of the skin by pediculi and dirt, sometimes called vagabond's discoloration, must be remembered. In rare instances the skin has been so deeply discolored in melanotic carcinoma as to be mistaken for Addison's disease. In exophthalmic goiter patches of pigmentation and leukoderma are common.

These various sources of pigmentation must be excluded and asthenia must be present before making a diagnosis of Addison's disease. After death the abundance of fat in the abdominal wall, in marked contrast with the general emaciation, has been frequently noted. The liver and spleen are often enlarged, as well as Peyer's patches and the mesenteric glands.

The prognosis is bad. Death may occur in a few weeks, especially when bronzing of the skin is slight or absent, and great prostration, vomiting, and diarrhea are present. It would seem easy to confound such a condition with typhoid fever or acute tuberculosis. Usually, however, the disease is protracted, lasting months or even years. In the longer cases periods of improvement may occur and hope be raised as to final recovery. Sooner or later, however, exacerbations are sure to occur, and the end is always the same.

In the present state of our knowledge of Addison's disease the treatment must be symptomatic. In general it is to husband and, if possible, to increase the patient's strength.

For obvious reasons cases are seldom diagnosticated until they are far advanced. At this stage quiet and, in some cases, absolute rest in bed are necessary, for sudden death in a number of instances has apparently taken place from syncope induced by slight exertion. The diet should be light and nutritious. Milk is often the best food. Arsenic and strychnin, iron, if there is anemia; ice, champagne, and hydrocyanic acid for the irritable stomach; bismuth for diarrhea, may all be used when indicated. If there is constipation, mild laxatives should be chosen which will not disagree with the stomach.

When the function of the adrenals shall be better understood important additions to our present knowledge of the etiology and treatment of Addison's disease will follow. Within the past two years a remarkable amount of thought has been directed to the ductless glands of the body, and the adrenals have not escaped investigation.

Oliver, especially, has been working with extract of suprarenal capsules, and has found that, in case of human beings, it is capable of producing an increase of vascular tone and a diminution in the size of the arteries. In other words, its effects are contrary to those of thyroid extract. Experimenting on animals, this investigator has shown that both alcoholic and aqueous extracts of the adrenals contain a powerful substance, which, on injection in extremely minute doses, produces remarkable physiologic effects upon certain parts of the nervous, muscular, and vascular systems.

Whether this is a useful substance, made by the adrenals from the blood, to be used as required to affect the circulatory system, or whether it is a poison carried to the adrenals for them to render harmless, is, according to Oliver, not yet known.

The therapeutic value of the animal extracts and other products of the animal system is perhaps not yet fully known or acknowledged. Enough, however, has been demonstrated in this direction to justify the hope that light will soon be shed on the treatment of Addison's disease.

THERAPEUTIC NOTE.

THE ANTISEPTIC TREATMENT OF TYPHOID FEVER WITH THE CHLORIN-QUININ SOLUTION.[1]

BY EMIL KING, M.D.,
OF FULDA, MINN.

IN a section of country like this one, where typhoid fever is met with a good deal every autumn, a knowledge of the most successful and at the same time the easiest treatment to carry out is necessarily very important. The younger members of the profession will bear me out in the statement that about all we are taught in regard to the treatment of this disease in the great medical seats of learning is that drugs are to be spurned and that the Brand or cold-bath treatment is the only proper thing. When, however, the practitioner in the country and smaller towns attempts to apply this method he is met by the prejudice of the laity and the expense, as trained nurses and bath-tubs are not within the means of the mass of the people. Thus we are forced to adopt some other line of treatment, and I am pleased to say that we have one that not only meets the requirements,

[1] Read before the Southwestern Minnesota Medical Society at the semi-annual meeting held at Fulda, July 11, 1895.

but gives better results and is more pleasant than the Brand plan.

In looking over the literature of typhoid fever for the last decade, one is surprised at the long list of drugs employed; prominent among them we find the coal-tar antipyretics and the antiseptics. Of all the various methods of treatment receiving professional sanction the one having antisepsis for its basis seems to my mind the most rational. We all know that in this disease the alimentary canal is a perfect hotbed of bacterial organisms; these are continually producing ptomains and toxalbumins, and both clinical and experimental observation shows that these poisons are absorbed and cause many of the symptoms of the disease. It seems entirely consistent to believe that bacteria other than the specific one cause much of the putrefactive fermentation, the fever-poisons, the softening, the breaking-down and perforation of the intestinal walls. None of the advocates of the antiseptic treatment claims that we can obtain an aseptic condition of the intestinal walls, but we do claim that we can keep the bacterial growths in small numbers and a low state of vitality, and that the bacterial poisons are very much lessened and consequently are not present to be absorbed. The almost entire absence of bowel-complications among the cases treated by this method seems to prove this assertion.

The antiseptics employed in the treatment of typhoid fever are many, and several have been found of value. Among these I may mention zinc sulphocarbolate, thymol, silver nitrate, salol, and carbolic acid. The main points in selecting one of these is to get a substance that is readily soluble, very diffusible, easily absorbed, is a powerful antiseptic, and which in overdose will cause no harm. The substance that best combines these advantages is, I believe, chlorin. This gas in solution was long ago found of great value in grave forms of ulceration of the throat, and we know that the disinfectant properties of lime depend upon the action of the chlorin present. It is readily absorbed and is not irritant to the tissues. It appears to stimulate the liver, kidneys, and all glandular structures, and cleanses and disinfects the ulcerative lesions of the bowel. Chlorin is superior to all other antiseptics in the treatment of typhoid fever, because it is diffusible, stimulating to glands, aiding elimination, is readily absorbed, and, I believe, more powerful than other available antiseptics. Unlike silver nitrate, zinc sulphocarbolate, salol, and other remedies, it is not decomposed into insoluble salts, and thus does not lose its effect.

The chlorin-quinin treatment was originated by J. Burney Yeo, of London, England, and has been employed by him and others with great success for about twenty years. During last fall and winter I treated in this way twenty-three cases of typhoid fever without a death or serious complication, and I can say that these cases ran a much safer and pleasanter course than those of a year before. The solution is prepared in the following manner: Into a twelve-ounce bottle are put thirty grains of potassium of chlorate, and to this sixty minims of strong hydrochloric acid added; a brownish-yellow gas is given off, and when the bottle is nearly filled with it a small quantity of water is added, the bottle thoroughly shaken, and the addition of water and the shaking being repeated until the bottle is filled. I now add the quinin, usually twelve grains. Syrup may be added in place of the water to improve the taste, though I find this unnecessary, for after taking the medicine for a few days patients do not seriously object to the bitter taste. We now have a solution containing chlorin and other gases, potassium chlorate, free hydrochloric acid, and quinin. The quinin is added for its general antiseptic and tonic properties. We do not wish its physiologic action. It may be given to small children in some other form, though it will not act so well, or it may be entirely omitted if for any reason contraindicated. The dose of the finished solution for an adult is a tablespoonful in half a tumbler of water every two hours. This quantity may be increased or decreased as necessary, the main point being to give enough to make the stools smell strongly of chlorin, to insure its thorough action on the intestinal coats and contents. It is a good plan to direct rinsing of the mouth after the medicine is taken, to prevent injury of the teeth. As soon as my diagnosis is made I order or prepare the medicine and continue its administration until the temperature has been normal for four or five days. For country practice I carry the ingredients and prepare the solution as needed at the bedside. Of course, the best results are obtained if the case is seen early, but even late the remedy will have a good effect.

In comparing the histories of my cases, twelve in number, treated with sponge-baths and other cold applications, antipyretics, salol, turpentine, etc., during the fall and winter of 1893, with those of cases treated by the method here described during the fall and winter of 1894, I find the following points in favor of the latter:

1. The temperature is materially affected, being appreciably lowered. It seldom rises above 102.6° F. after the medicine has been administered for two days.

2. There is an almost entire absence of nervous symptoms. The so-called typhoid condition does not develop. The patient is usually able to get considerable sleep and the headache soon disappears. In a case seen during May and June, 1894, the typhoid condition was very marked, and the patient was entirely oblivious to surroundings for over a week. This case was treated with sponge-baths and zinc sulphocarbolate and salol, and though at death's door for weeks, thanks to a magnificent constitution, recovery finally ensued.

3. The general condition of the alimentary canal is much better. The foul tongue clears to some extent, so that it may even lose its peculiar character; the stomach retains nourishment better; diarrhea is seldom severe; and tympanites does not develop except over a limited area in the right inguinal region.

4. The duration of the disease is distinctly shortened and convalescence is more rapid. Many cases will show a normal temperature by the eighteenth day, few going on to the twenty-fourth. Convalescence is more rapid because the patient is not so weak. Bedsores did not develop in any of my cases last fall, while this complication occurred to me in two cases the year before.

5. Complications are fewer and the mortality is greatly lessened. In none of my cases did any serious complications appear. Two cases had slight attacks of bronchitis, but these were short and were easily controlled. Accurate statistics of the mortality under this treatment are wanting. J. Burney Yeo had seen only two deaths under this treatment up to June, 1894, and he claims to have treated a great many cases. Dr. O'Connor, of Buenos Ayres, S. A., reports one-hundred consecutive

cases, with only two deaths. In this country the only cases reported, so far as I know, are three by Dr. J. Mosley Kerr, of Columbus, Ohio, and now twenty-three by myself; all without deaths.

In beginning the treatment of a case of typhoid fever seen in the early stage the first thing to consider is absolute rest in bed. The room must be airy, the bed being placed so as to avoid drafts, although ventilation should be free. I also favor plenty of sunshine when not objectionable to the patient. The bed itself should be smooth, not too soft, and the covering need only be light. Cleanly surroundings are always to be desired. I now begin to prepare the alimentary canal, if the state of the fever does not need immediate attention, by ordering a thorough purge, giving one grain of calomel and two of sodium bicarbonate every hour until the desired result is secured, the object being to remove fecal masses and all fermenting substances. I select calomel on account of its stimulating influence on the liver and intestinal glands, and also for its antiseptic effect. The beneficial effect of the purge is shown by a drop in the temperature and a lessening of the abdominal tenderness.

In the management of a case of typhoid fever the food-question early assumes importance. It is now very general to restrict the patient to an exclusive milk-diet; from one-half to three quarts per day is the amount recommended by writers. In my limited experience I have not seen a case that would voluntarily take as much as the latter quantity. The absorbent powers of the gastro-intestinal mucosa are so much impaired that, I believe, this quantity cannot be digested. If physicians will carefully examine the stools of patients taking from three to six pints of milk, they will find that quantity passing away as the "pea-soup" stool; they will also find the curds responsible for much of the diarrhea. According to the pathology of the disease, it should be our aim to afford rest to the inflamed bowel, and to do that we must not give more food than can be digested. Any amount remaining will not only serve as a nidus for fermenting germs, but will induce peristaltic movements, thereby causing diarrhea and also increasing the absorption of noxious poisons. To make milk easier of digestion it should be diluted with water, and drunk only in small quantities at a time. When milk disagrees, buttermilk or icecream may be substituted. Home-made beef-tea and thin gruels and soups must at times be given, as all mill-preparations may disagree. I also permit the use of fruit-juices, as of the lemon and the orange; these form a pleasant addition to the limited diet-list. Tea or coffee may be permitted, as there is no good reason why the use of two such good cardiac stimulants should be prohibited. I make it a rule never to urge the patient to take nourishment as long as he is rational; of course, should the typhoid condition set in, then forced feeding may become necessary.

Of greatest importance in the treatment of typhoid fever is the internal use of water. Always let the patient have all he wants; in fact, the more he drinks the better. Drinking large quantities of water has a calmative influence on the nerve-centers; it assists in the oxidation and elimination of effete matter, the secretions of the kidneys and skin are increased, and the tension of the circulation is relieved. The internal use of water, then, tends to lower temperature, increases elimination, and decreases nervousness. Authorities recommend that from four to six quarts should be drunk daily. My patients would not take that much, but I have them drink over two quarts with their medicine.

Usually, as soon as the temperature drops to normal the appetite returns, and we are besieged with the question, "What can the patient eat?" In practice outside of a hospital we find it difficult to keep the patient on a liquid diet for ten days after the temperature is normal. I usually begin on the fifth or sixth day by permitting the patient to eat a small quantity of toasted bread, an egg prepared according to his wishes, or other food, such as custard, oatmeal, or farina. Soon we can permit small pieces of meat and some vegetables; the diet being brought back to the normal in about two weeks.

Of the special indications perhaps the height of the fever is the most important. It is generally agreed that temperatures over 102.6° F. long continued are dangerous, by inducing depression of the vital centers and a cloudy degeneration of the muscular structures, especially of the heart. This temperature is the line, on crossing which the patient, in all well-ordered hospitals, is now plunged into a cold bath. I agree with Brand and his followers that this procedure powerfully depresses temperature, and at times may be necessary to save life; but I do not believe in subjecting the patient to it three or more times a day, when I can attain the desired result by easier and pleasanter methods. When the temperature rises above 103° F., and this is seldom, I order a cold pack, or sponging of the abdomen and chest, and cold applications to the head. Headache, which so often is due to high fever, is easily relieved in this way; some alcohol or vinegar may be added to the water applied. In cases of hyperpyrexia, when symptoms of danger are present, I should not hesitate to use the cold bath, as it may be the quickest means of saving life. The coal-tar antipyretics in occasional small doses do no harm, but I do not regard them as necessary.

The so-called typhoid condition calls for energetic stimulation; and here good brandy, ether, strychnin, and atropin are of great service. In one case (already mentioned) seen rather late in the course of the disease, I resorted, among other measures, to the rectal injection of tincture of asafetida with marked benefit. Forced feeding by the mouth or rectum may now be imperative, and water to drink must not be forgotten. It is only in this class of cases that I employ alcoholic stimulation, though alcohol is also of value in certain cases as a stomachic during convalescence.

The various parts of the alimentary canal call for constant attention. The mouth and tongue are generally in a bad condition, and frequent washing with an antiseptic solution, such as Dobell's well-known combination, is grateful to the patient. I find that unloading of the bowels, even when there is diarrhea, improves irritability of the stomach; if not, this is treated by the usual methods. Diarrhea is treated by withholding excessive quantities of food, observing the same rules as when treating a case of cholera infantum, the stools being frequently examined for undigested particles, and by the use of such remedies as bismuth salicylate, opium, etc. Opium-suppositories are of benefit to allay tenesmus and at times to induce sleep.

Overfeeding is, I believe, largely responsible for tympanites. The internal administration of oil of turpentine

and oil of anise will usually relieve the distention; rectal injection of asafetida and glycerol will also be found of benefit; and in extreme cases the passing of a rubber tube into the bowel or even puncture may be resorted to. But these extreme cases are usually fatal. Constipation may be relieved by the use of castor-oil or some other gentle laxative. I am satisfied if the patient has one stool every other day, provided, of course, no symptoms referable to this cause appear. During convalescence the mineral acids and bitter tonics, of which strychnin is the best, are of benefit. In cases of protracted convalescence the internal use of oil of turpentine, as advocated by George B. Wood, is one of the best remedies. I shall not in this article touch upon the complications of typhoid fever.

I cannot resist the temptation of comparing, as I see it, the comparative value of this antiseptic and the Brand method of treatment. The antiseptic plan, intelligently carried out, follows closely the pathology of the disease. We aim to prevent as much as possible the formation and absorption of toxic substances; we keep the alimentary canal comparatively empty, and hence do not have the fermenting and macerating effect on the intestinal ulcers. By doing this we avoid perforative complications, which are so largely responsible for the mortality. Under this treatment the temperature does not often rise above the bath-line; hence this measure is seldom needed. The duration of the disease is materially shortened and convalescence is more rapid. These are the reasons why the general results under this treatment are better than under Brand's. The mortality under the Brand treatment in this country varies all the way from 3 to 16.6 per cent., relapses occurring in about 13 per cent. of all cases, and the duration of the disease being about forty-four days, the most surprising thing being the large number of relapses. I consider the Brand treatment open to the following objections: It is a symptomatic treatment entirely, losing sight of the pathologic indications, as rest and diet, through the bugbear, fever. As at present carried out, the patients are indiscriminately subjected to the same measures, that is, a dose of brandy, ice-water to the head, and immersion in water at a temperature of 70° F. for from ten to fifteen minutes, with friction of the body. Otherwise the patient is treated symptomatically and large quantities of milk are forced upon him. In small towns and in the country this method is difficult to carry out, the nurse usually being some overworked member of the family. Bath-tubs are not found in most of the houses, and they are expensive, though portable ones are made which the physician can purchase for use by his patients. Another important objection is the opposition of the laity, as very many people regard it as little short of barbarism to take a fevered patient from his bed and plunge him into a cold bath. From the outline of treatment given, it may be seen that I do not object to hydrotherapeutics under certain circumstances, but I strongly urge a combination of the valuable points of each, and to treat the disease under consideration, not by its symptoms, but in the light of our present knowledge of its pathology. Does it not seem right to direct treatment to the point where the fever-poisons are generated and thus make a cold bath unnecessary? Those who try it will be sure to see the picture of the disease change for the better.

MEDICAL PROGRESS.

Excision of the Rectum for Malignant Disease.—Heuston (*British Medical Journal*, No. 1795, p. 1141) describes an operation for excision of the rectum for malignant disease that he has performed in two cases, and for which he claims that it preserves the normal functions of the bowel, that subsequent stricture is not so liable as after the usual operation, while convalescence is rapid, the mortality is low, and the disease is no more liable to recur than after more extensive operations.

An incision is made from the rectum to the coccyx, which, being in the median line, severs the attachment of the external sphincter and levator ani muscles to the ano-coccygeal ligament. The rectum is now separated from the surrounding cellular tissue and clip-forceps are applied to the rectum at the commencement of the ampulla, below which the bowel is divided. The attachments of the levator and sphincter muscles to the bowel are thus not interfered with and hemorrhage is restrained. The rectum being now completely divided above the internal sphincter, there is not much difficulty in bringing it downward and backward through the median incision, its separation from the prostate and the base of the bladder being facilitated by having to draw it backward. Clip-forceps are applied above the diseased portion, which is removed by scissors. The upper portion of the bowel is fixed by deep sutures, attaching it, about an inch above its cut extremity, to the recto-vesical fascia and levator ani and the peritoneum. In applying these sutures, care should be taken that the mucous coat of the bowel is not penetrated. A second row of sutures is applied between the cut extremity of the bowel and that portion which had been originally left below; these sutures should penetrate the entire thickness of the bowel in both instances. The object of the upper row of sutures is so to fix the bowel as to obviate the danger of the sutures uniting the cut extremities of the bowel tearing through. The incision from the anus to the coccyx is now closed, the most anterior sutures including the posterior aspect of the bowel, but not penetrating the mucous coat. The levator ani and sphincters will thus have their normal relation to the extremity of the bowel preserved. It might be thought that the lower portion of the bowel is in danger of sloughing, owing to the superior and middle hemorrhoidal arteries being cut away from it, but the hemorrhoidal branches of the pudic arteries are sufficient to maintain its vitality.

Chloroform-anesthesia.—As a result of a study of the question of chloroform-anesthesia, Brunton (*Lancet*, Nos. 3750 and 3751) has arrived at the following conclusions: Experiments on animals have conclusively shown that chloroform given by inhalation and not blown artificially into the lungs kills by paralyzing the respiration. Clinical observation has shown that cases of simple danger without death during anesthesia are due to failure of the respiration. Cases of death may arise from the same cause, but may also be due to stoppage of the heart (syncope) or to stoppage of the heart and respiration together (neuroparalysis). The most common cause of neuroparalysis has been found by Caspar to be throttling, strangling, and drowning, which kill by neuroparalysis as often as by asphyxia. Anesthetics have no

tendency to produce neuroparalysis except when they are given in such a manner as to irritate the respiratory passages, either mechanically or chemically. On the contrary, they tend to lessen shock. During imperfect anesthesia, both at the very commencement of administration of an anesthetic or during recovery from its influence, choking may occur and cause death by neuroparalysis as well as by asphyxia. The neuroparalysis is the result that is most to be dreaded, as simple asphyxia may usually be recovered from if artificial respiration be maintained. It is, therefore, most important in the administration of anesthetics to avoid anything that is likely to interfere with respiration, as such interference may act like throttling and cause death by neuroparalysis. During complete anesthesia, the reflexes being almost or entirely abolished, there is little risk of neuroparalysis, but the nerve-centers being weak there is more of asphyxia. At the commencement of administration and during recovery, when the reflexes are present but may be deranged, the danger of death from neuroparalysis is greatest, and the respiration then requires to be watched with especial care. Although there may be no objection to the anesthetist keeping his finger on the temporal artery, and thus unconsciously watching the pulse, yet the respiration must be his main care, and anything that will withdraw his attention from it is studiously to be avoided.

Monarticular Rheumatism.—HEIDENHAIN (*Deutsche medicinische Wochenschrift*, 1895, No. 31, p. 496) calls attention to the occurrence of cases of articular rheumatism with involvement of but a single joint, and an absence of manifestations of an acute febrile disorder. Pain is present usually, but in slight degree. Other causative affections, such as traumatism, gonorrhea, osteomyelitis, tuberculosis, syphilis, were with certainty excluded and relief was afforded by the administration of full doses of sodium salicylate. In the cases observed the shoulder-joint was most frequently involved; then in the order of frequency the wrist, the elbow, and the ankle. In an additional number of cases two joints were similarly involved. The question is raised whether an insidious endocarditis may not develop in the course of attacks of this kind.

A Tubercle of the Intima of the Aorta.—At a recent meeting of the Société de Biologie, HANOT and LEVI (*Compt. Rend. Hebdom. des Séances de la Soc. de Biologie*, 1895, No. 22, p. 471) reported the case of a man, sixty-one years old, dead of tuberculosis, in which at the upper part of the thoracic aorta in the interval between the origin of two intercostal arteries was found a tubercle, of roundish form, grayish color, firm consistency, the size of the head of a pin, and slightly projecting within the lumen of the vessel. Upon section this was found to be a true tubercle, free from vessels, presenting a few giant-cells, together with tubercle-bacilli. The formation was evidently of recent development. Its center was in process of caseation. It was developed in the subepithelial layer of the vessel at the level of the fibrillar substance, which formed about it an incomplete sheath.

Diplococci in the Blood of Patients with Scarlet Fever.—CRAJKOWSKI (*Centralblatt für Bakteriologie und Parasitenkunde*, B. 18, Nos. 4 and 5, p. 116) has reported the results of examinations of the blood in thirteen cases of scarlet fever, in which he found, both upon direct examination and upon culture, diplococci, such as he had not observed in a large experience under other conditions. The organisms stained with difficulty, and were readily decolorized. They did not stain by Gram's method. A capsule could not be discovered. The organisms developed readily upon various culture-media. Inoculations of pure cultures were pathogenic for mice, and the same diplococci could be isolated from the blood of these animals.

Gangrene of an Extremity in the Sequence of Typhoid Fever.—QUERVAIN (*Centralblatt für Innere Medicin*, 1895, No. 33, p. 793) has reported the case of a man, twenty-five years old, in which in the course of an attack of typhoid fever gangrene of the right lower extremity set in, eventually requiring amputation above the knee. The patient ultimately recovered. On examination of the amputated member the popliteal artery and vein were found occluded by thrombi, and an abscess in the muscular tissues below the knee. Examination of the pus from this collection disclosed the presence of typhoid-bacilli.

THERAPEUTIC NOTES.

In the Treatment of Frost-bite BOECK (*Monatshefte f. Praktische Dermatologie*, Band xxi, No. 4, p. 171) recommends the following formula:

Take—Ichthyol, Resorcin, Tannic acid, of each . . 1.00
Water . . . . . 5.00—Mix.

Apply with a brush at night.

Should this for one reason or other be objectionable, the following formula may be substituted:

Take—Resorcin 2.00
Mucilage of gum arabic, Water . . . each 5.00
Powdered talc . . . 1.00—Mix.

Apply topically with a brush.

Urotropin is the name given by NICOLAIER (*Deutsche medicinische Wochenschrift*, 1895, No. 34, p. 541) to hexamethylentetramin because of its influence upon certain urinary constituents. He has found this agent in solution, as well as the urine of patients to whom it was administered, capable of dissolving uric-acid concretions. The substance appeared also to check ammoniacal fermentation, the urine of individuals using it remaining perfectly acid, and in some instances it acted as a diuretic. An antiseptic effect was also observed. The drug has been successfully employed in the treatment of cystitis. The doses given ranged from seven-and-one-half to ninety grains daily. Large doses were attended with a sense of burning, referred to the bladder on micturition.

For Pulmonary Tuberculosis.—Take

Calcium phosphate, Menthol . . . each 4 grains.
Sodium bicarbonate . 3 "
Powder of nux vomica, Iron lactate . . each ¾ grain.—M.

To be taken four times a day with food. MARAGLIANO—*Journal des Praticiens*, July 27; *Med. Chron.*, August, 1895.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM, IN ADVANCE $4.00
SINGLE COPIES 10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM . . . 7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 14, 1895.

INEBRIETY.

DR. NORMAN KERR is among the foremost of those who regard inebriety as a disease. He has written an elaborate treatise on this subject, and the third edition of this work, now before us,[1] is undoubtedly the most representative work on the subject in the English language.

The difficulty that we experience in following Dr. Kerr is chiefly in grasping firmly his idea of what really constitutes the disease which he denominates "inebriety." This term, as connoting a distinct morbid entity, has always been somewhat of a will-o'-the-wisp to us, and we confess that it remains so after a study of Dr. Kerr's book. We do not wish to appear to be behind anyone in recognizing the baleful pathologic effects of alcohol upon the human system. That it is a most potent poison, with well-recognizable anatomic changes in its train, is among the fundamental facts established by modern pathology. Just as syphilis, gout, and rheumatism work their characteristic havoc upon tissues, so does alcohol. This fact goes without saying. But the method of approaching the study of the effects of alcohol differs with some writers, among whom Dr. Kerr is prominent, from that which is customary and legitimate in the study of the effects of these other pathogenic substances. It is this distinction that we wish to point out, because it is emphasized to our mind in Dr. Kerr's book.

This distinction may be said to be shown in the fact that Dr. Kerr and his followers take an apriori view of inebriety. The approved methods of modern science lead to a study of particulars, and from them to the formation of a general conclusion. We study symptoms first before we begin to construct a picture of a disease. The ravages of syphilis have for years been depicted by master-minds until now we have a tolerably distinct clinical picture of what is meant when we speak of a syphilitic patient. The same statement may be made of the ravages of alcohol as studied by the general pathologist. The effects of the poison on nervous, gastric, hepatic, and renal tissues are recognizable; they constitute, in a sense, a morbid entity—the complexus of the results of the action of the poison.

This method of study is not exactly that of the followers of Dr. Norman Kerr, although they avail themselves of it as an adjuvant to their own lucubrations. Dr. Kerr, as we have said, pursues primarily an apriori method. He constructs, first of all, the image of a disease, and then he groups about it the findings of pathology. This prior image is the hypothetic entity which he calls "inebriety." This disease, if we read Dr. Kerr correctly, is pre-existent to the specific effects of alcohol. It may, in fact, although the expression seems paradoxic, exist entirely independent of indulgence in alcohol. It is something innate in the subject—a potentiality, a pathologic analogue to original sin. This seems to us to be rather a theologic or metaphysical method of contemplating disease. The *corpus morbi* pre-exists in the tissues, based upon heredity and fortified behind the postulate that the sins of the fathers are visited upon the children to the third and fourth generations. A tippler *in embryo*, the unlucky wight grows into a sot *in posse*, lives as a drunkard *in essentia*, and may or may not become a guzzler *in esse;* but all the time he is an "inebriate." We are not aware of any other department of medical science in which this method is followed, except by some extremists in psychiatry and by some of the apostles—now much in evidence—of that "abnormal man," Lombroso. Hence we judge that this scheme is worthy of note.

[1] Inebriety or Narcomania; its Etiology, Pathology, Treatment, and Jurisprudence. Third edition. New York: J. Selwin Tait & Sons.

Let us insist here, however, that we do not intend to disparage a fair interpretation of the doctrine of heredity; or of the science that finds in vicious propensities, as displayed in some individuals, the signs of a psycho-neurosis. The inherited tendency to alcoholism is an undoubted fact in many inebriates, and furnishes one of the most important though obscure problems of this grave question. This tendency has a somatic basis, and science may claim as her legitimate function the investigation and establishment of the marks of this species of obliquity. We merely hesitate, at this stage of our knowledge, to erect upon a mere tendency or appetence, however closely allied that may be to the morbid impulses of degeneracy, a distinct morbid entity and label it as a disease.

These difficulties have surrounded Dr. Kerr in his attempts to describe and to define "inebriety." He naturally finds the closest parallels of inebriety in insanity, and points out the resemblances of the various effects of alcohol, as acute intoxication, delirium tremens, *mania a potu*, and the persecutory delusions of the chronic drunkard, to the various symptoms of insanity. These resemblances, however, do not prove an identity. These more or less evanescent effects of alcohol are surely not the symptoms of a constitutional malady, else every man who experiences them must be, in Dr. Kerr's sense, a constitutional "inebriate."

So, too, of the anatomic changes produced by alcohol. If inebriety is the constitutional and hereditary malady described by Dr. Kerr, it has existed *prior* to the establishment of the degeneration of the tissues caused by alcohol. These are only the after-effects of the disease, its sequelæ. The study of the disease as an hereditary neurosis must be pursued along other lines. Cirrhosis of the liver can hardly be regarded as one of the symptoms of "inebriety."

It is but fair to Dr. Kerr to say that he has undertaken an exhaustive study of the etiology of inebriety; and in this respect he has made valuable contributions to our knowledge, and has done much toward establishing this subject upon a scientific foundation. His book is rich in data that go far to enlighten the student upon the subject of the drink-habit.

From the practical standpoint of treatment and jurisprudence Dr. Kerr's book is deserving of all praise. Both as a therapeutist and as a philanthropist his aims and his attainments lift him far above the level where he can be seriously affected by a discussion of mere terms; and although we have concerned ourselves here briefly with such a discussion, which we deem fair and advisable, we are not unmindful of the highly important work of one whose name is forever honorably associated with an enlightened and scientific attempt to combat the grave curse of drunkenness.

INDIVIDUALISM.

MEN are a good deal alike, both physiologically and psychologically. We have come to count with confidence upon finding the trunk of the ulnar nerve just under the internal condyle at the elbow in subjects of all ages, races, and sizes, and to rely upon the effect of castor-oil in any alimentary canal of whatever length or capacity—and upon such generalizations of similarity science is based. Ninety-nine men out of every hundred exposed to certain stimuli, either physical or mental, will react in exactly the same manner. This fact enables us to lay down rules of treatment which will be found to apply to the vast majority of our patients. We must, however, remember that the "average man," like the "typical case," does not exist outside of the text-books. In any given case it is always an individual and not a mere unit that we have to deal with.

The naturalist sometimes speaks as if it were a wonder that organisms tend to vary. But to one who studies any given form closely enough the wonder is that beings of such marked individuality succeed in resembling one another so closely. Take the leaves of a forest, for instance. At first glance they appear as one uniform mass of specks of verdure, but on closer view they are found to present striking differences, which divide them into oak-leaves, ash-leaves, etc. Then, on closer study still, the leaves of each maple-tree are found to be different from those of every other member of its species; and finally of a thousand leaves on the same branch of any single tree, absolutely no two are exactly alike in color, shape, and veining. The same is true of the human species. At first glance all its members are extremely similar, especially if they happen to belong to a race or tribe with which we are but little acquainted. Most Caucasians on first acquaintance declare that all Chinamen are exactly alike, and the same statement is often heard from persons of Northern birth in regard to negroes. A very brief residence among

either race is, of course, sufficient to dissipate any such idea.

We have grown quite accustomed to the fact that even among persons of the same race, age, and social condition, the countenance varies so greatly that no two faces are the same, and not once in five-thousand individuals does even sufficient similarity of features occur as to cause persons to be mistaken for one another. Even among children of the same father and mother it is extremely rare for family-likeness to prevail to such an extent as to cause confusion among intimate friends, although it may often do so among strangers. The marvel really is that we succeed in being so much alike.

One of the most extraordinary proofs of the intenseness and minuteness of our individualization is the arrangement of the cutaneous papillæ upon the pads of the fingers and thumbs. These are usually grouped in curious concentric whorl-like lines, and, almost incredible as it may seem, are never arranged in the same pattern in any two individuals. So widely and persistenly do they differ that Galton has recently proposed to use them as a means of identifying criminals and soldiers, and he has drawn up a scheme of classification of them for that purpose. This has just been investigated by a committee appointed by the British Government, which has made such a favorable report upon it that it will probably be put into actual practice very shortly by the English police-authorities. The principle itself is not new, for a similar method of identification has been in use in China for centuries; but the application and system of classifying are extremely ingenious. By means of it a given finger-point can be identified with its fellow in a collection of several thousands in a few minutes. Instead of the troublesome, unreliable, and cumbrous photographs of the "rogues' gallery," the criminal's portrait is taken by simply smearing the tips of his thumb and finger with lampblack and pressing them upon a sheet of white paper, which can then be classified and filed. No amount of dodging or grimacing will avail to distort *that* "mug," as he expressively terms his countenance or portrait. It is said that the value of the method has been shown in a most dramatic manner by the conviction of a murderer from the print of his bloody fingers on the white wall above his victim.

It would thus appear that we are very literally individual *aux bout des ongles*, as the French say, "to the tips of our fingers." And does not this individualization extend to the alimentary canal, the vascular system, the whole organism, in fact? Some of our throat-cases can be recognized almost as readily by their fauces as by their faces and family-likenesses traced in the same region. No two ears are exactly alike, and, next to the eyes and mouth, the ear furnishes one of the most accurate signs of temperament and tendencies that we possess.

This individuality is not merely anatomic, but functional as well. The numerous cases that have been reported, and some of them seen personally by all of us, of severe toxic symptoms from a whiff of cocain-spray; of acute distress from a tenth of a grain of morphin; of gastric crises, and profuse urticarial eruptions following a single grain of quinin, are living proofs of it. So, also, are the cases in which acute toxic symptoms are invariably produced in certain individuals by the ingestion of the smallest quantities of strawberries, of clams, of veal, of apples, nay, even of eggs and of wheat-flour. Probably one-third of our patients will tell us that they "can't eat" some article or other of ordinary diet on account of the almost poisonous effects produced by it. Literally, "What is one man's meat is another man's poison." The "personal equation" is one of the most important factors in therapeutics, and we must ever bear in mind the old rule to treat the patient, not the disease.

EDITORIAL COMMENTS.

"*If Christ Came to Chicago?*"—When a well-known journalistic mountebank wrote a book with the foregoing title he little thought how soon his imagined touchstone would be actually applied. According to many faithful believers, Christ, or, at least, his healing power, has already come to Chicago incarnate in the person of one John Alexander Dowie. The World's Fair was his Feast of the Passover, on the occasion of which he came down to the great city, and his method of teaching is by the bill-board, the ten-foot sign, and the illustrated broad-sheet, instead of by the parable and the lilies of the field, but his spirit and results are said to be identical with those of the Nazarene. The blind do hear, the dumb see, and the lepers have their tubercle-bacilli demonstrated unto them. Thousands of witnesses stand ready to testify that they have been healed, by the laying on of Mr. Dowie's hands, of every disease that their imagination could suggest, and some of them of several diseases. For instance, a whole congregation declare upon oath that in the healing, in their presence, of a woman who was partially blind, "with the falling of the scales there also came a visitation *which stripped the body of locomotor ataxia.*" This document can, however, hardly be considered as fully authenticated, as neither the eye-

scales nor the peelings of locomotor ataxia are appended thereto as evidence, in properly certified envelops.

One believer certifies that he was cured instantly of "rheumatism, hernia, kidney and liver disease, and the tobacco-habit;" another lost at one fell swoop "a number of internal cancers, tumors, etc.;" and yet another, "many diseases, including heart-disease, lung-disease, spinal irritation, iritis, and paralysis." It is really to be doubted whether the shock of having so many removed at once might not prove serious to delicate constitutions. More marvellous yet, three or four enthusiastic converts declare that one of their legs has been lengthened from three to four inches, but unfortunately they fail to state whether they were "pulled" or what means were used to secure the result. One of these had been "marked for the grave by all the doctors," after the well-known habit of the medical profession. Other than this, however, there is not a scrap of evidence of any scientific value as to the genuineness of either the cures or the diseases. One woman quotes Dr. Sanger Brown and "an association of physicians, some sixty in number," as authority for the fact that she had "idiopathic muscular atrophy." But Dr. Brown has no better taste than to come forward and say that she had only a "most serious attack of hysteria"—just as if anyone would take his word against that of a lady, in a matter of this sort.

But this is a faithless and an unfeeling world, and, incredible as it may seem, in spite of hundreds of such pathetic testimonials as the foregoing, Mr. Dowie's neighbors on Edgerton Avenue are bringing suit for his removal as a nuisance. They advance the sordid and heartless claim that the continual procession of the halt, the maimed, and the blind destroys the comfort of their homes and depreciates the value of their real estate. 'Twas ever thus since the days when the devils were driven into the herd of swine; "the people of that country besought Him that He would depart out of their coasts." And if pork instead of real estate had been affected in Chicago, something much more drastic than a mere legal injunction might have been resorted to. It was more than suggested in Mr. Stead's book that Christ might not find Chicago an altogether desirable place of residence, but that Chicago would bring suit to have Him abated as a nuisance; reality has brought a plight beyond the power of even his flatulent imagination.

The moral of this little episode is simply that, with all their credulity, all the laity cannot be "fooled all the time." The charlatan, under whatever mask of sanctity or of science, will be surely discovered sooner or later. There is only one set of laws for this universe, and fraud will surely be detected and punished, either under the moral, the scientific, or the commercial code, and generally under all three.

The Revival of the Index Medicus.—We are informed by Mr. George S. Davis, who has hitherto so generously supported the burden of publishing the *Index Medicus*, that in addition to the forty-eight subscriptions at $25 each, noted in THE NEWS of August 31st, there were received up to September 5th, inclusive, the following twelve:

Albany, N. Y.: Melvin Dewey (New York State Library).

Ann Arbor, Mich.: Medical Department University of Michigan, Victor C. Vaughan, M.D., Dean.

Baltimore, Md.: Dr. Charles O'Donovan.

Buffalo, N. Y.: Dr. F. W. Henkel.

New Orleans, La.: S. W. Deland (Orleans Parish Medical Society).

New York City, N. Y.: Dr. Fred. H. Wiggin.

Paris, France: Dr. Charles E. Sajous.

Philadelphia, Pa.: Dr. John B. Roberts, Dr. E. E. Montgomery.

St. Joseph, Mo.: Charles Wood Fassett (Secretary American Medical Publishers' Association).

San Francisco, Cal.: Dr. D. W. Montgomery (San Francisco Medical Society).

Syracuse, N. Y.: Dr. Henry L. Elsner.

The following additional list of seventeen has been received by Dr. J. S. Billings up to September 6th, inclusive:

Albany, N. Y.: Dr. Samuel B. Ward.

Brattleboro, Vt.: Dr. Henry D. Holden.

Cleveland, Ohio: Cleveland Medical Library, Dr. Dudley P. Allen, Dr. Henry K. Cushing.

Edinburgh, Scotland: Mr. Young J. Pentland, Pubr.

Lille, France: Bibliothèque Universitaire.

Paris, France: Dr. Charles Richet.

New York City: New York Academy of Medicine, Dr. George T. Elliot, Dr. Willy Meyer.

Philadelphia, Pa.: Dr. W. W. Keen, Dr. J. William White, Library Pennsylvania Hospital, Dr. William B. Van Lennep, Carl V. Vischer.

St. Paul, Minn.: Dr. C. A. Wheaton.

Now that medical men are returning from their summer holiday, that the medical colleges are reopening, and that the medical societies are resuming their meetings, the necessary list of 200 subscribers to insure a resumption of publication should soon be completed. Failure in this direction would be discreditable to say the least. Subscriptions should be sent without delay to Dr. John S. Billings or Dr. Robert Fletcher, at the Library of the Surgeon-General's Office, U. S. A., Washington, D. C., or to Mr. George S. Davis, Detroit, Mich.

Medical Competition and Pictures.—Every person has been amused, as well as disgusted, by the rage for illustrations that has seized upon the community. The old-time advertisements of the powers of the actor or the virtues of some nostrum are now replaced by portraits and illustrations infinite in number and variety and execrableness. The "regular" profession is imitating the quacks in this respect, and catalogues, prospectuses, and reports of sanitaria and hospitals may contain more pages of pictures than they do of text, and what little text there is is largely taken up with lists of the apples, clothing, potatoes, etc., contributed, the forms of bequests, the appeals to endow free beds, the records of gifts and expenditures, and all that and all the rest. We have before us the report of a large hospital for the insane, which in about forty pages has twenty-three illustrations of the buildings, grounds, parlors, bed-rooms, corridors, painting-rooms, dining-rooms, gymnasia, and what not more. Evidently, wealth, luxuries, flowers, and elegance galore are here the reward of insanity, and certainly no other institution can compare with this! Charity, civilization, and science here clasp hands in a bond of union. But we cannot help wondering by what right money given for the cure and care of the insane and the

sick is expended in photographing, engraving, and printing expensive illustrations like these. Making a business out of charity, money-making by begging, is evidently a growing and significant habit, not only of the tramp but also of the physician. We have public laws against begging—but it is plain that there are beggars and beggars.

The Names of Journals.—We wish mildly to protest against the growing custom of dubbing a journal by some other name than that it has given itself. It is one of the privileges of freedom that a man may be allowed to have the name he chooses, or that was chosen for him by his parents. It is a bit of unnecessary work to write and print supernumerary words as the title of a journal. If one wishes to learn where a journal is printed or where its editors and publishers live, these objects should be easy of fulfilment, but in mere quotation why say *The London Lancet, The New York Medical Record*, etc.? The names of these journals are not those given. Titles are long enough at best. At the present rate of progress we shall soon have to say *The Chicago Journal of the American Medical Association* and *The London British Medical Journal*, and eventually the street addresses may have to be added to the title. We are simply tired of seeing quotations from a worthy journal given as from *The Philadelphia Medical News*, when, of course, there is but one *Medical News* in the world.

The Vitapath and the Law.—It is pleasant to chronicle the fact of lay indignation at the enormity of quackery. It seems that in Cincinnati a man died without medical attention other than that of a "vitapath," who was arrested and fined for practising without a licence. The *Cincinnati Medical Journal* says:

In imposing sentence Judge Dustin denounced the Campbells. He said: "Men who knowingly go into a sick-room and prevent anything being done for a dying man by silly incantations and laying on of hands, are responsible for his death, and ought to be on a par with a murderer in the eyes of the law. God help the dying man who relies upon you or any of the so-called graduates of his quackery. You speak of vitapathy being of a higher power than medicine, and you say you ordain ministers at the same time you matriculate vitapathic physicians. Your methods are an insult to intelligence, their practice is a criminal abuse of ignorance, and your college a disgrace to civilization."

REVIEWS.

The Science and Art of Obstetrics. By Theophilus Parvin, M.D., LL.D., Professor of Obstetrics and Diseases of Women and Children in Jefferson Medical College, Philadelphia. New (3d) edition. Octavo, pages 677. Cloth, $4.25; leather, $5.25. Philadelphia: Lea Brothers & Co., 1895.

This, the third edition of Parvin's *Obstetrics*, will be appreciated by the student and practitioner, as well as by the specialist, on account of its concise and comprehensive treatment of the subject as it stands to-day. The most notable feature of the present edition is the arrangement, the author dividing his subject into two parts, the first including the physiology, from the beginning of pregnancy to the end of the puerperal state, and the second the pathology, treated according to the different periods. The therapy of the second part includes the important surgical procedures that have increased in prominence since the appearance of the earlier editions of the work. The arrangement noted is equally convenient with that usually adopted, and is, at the same time, more comprehensive and scientific. Specifically we would call attention to the description of Pinard's method of dislodging the foot in what the author calls the femoral variety of pelvic presentation; and to that of the mechanism of rotation in occipito-posterior positions of the head, in which the back of the child must be included among the determining factors in anterior rotation; also to the added series of illustrations, especially those included in the chapter on ectopic pregnancy, which, in itself, is a comprehensive *résumé* of the subject.

The absence of a more complete treatment of the bacteriology of puerperal septicemia is, perhaps, to be accounted for by the importance this branch of the subject has assumed as a special study rather than by a want of appreciation of its value in this connection.

One of the most valuable features of the present edition is the complete list of references appearing with the subject-matter in the body of the book. The author's bibliographic knowledge and his extensive obstetric experience and literary ability have been brought to bear in maintaining his work in the front rank among the most practical and scientific medical books of the day.

The care with which the cuts and plates have been executed and the general style of the work call for a word of appreciation for the efforts of the publishers.

Le Phénol Sulforiciné dans la Tuberculose Laryngée. Par Albert Ruault.

Phenol Sulforicinate in Tuberculosis of the Larynx. By Albert Ruault, M.D. Paris: G. Masson, 1895.

Phenol sulforicinate is a liquid composed of phenol dissolved in sodium sulforicinate by means of a water-bath at a moderate heat. According to the number of parts in 100 of phenol (sodium sulforicinate forming the balance) the solution is designated as 20, 30, or 40 per cent. That which is found to be of the greatest service as a topical application in tuberculosis of the larynx is the 30 per cent. solution. The 40 per cent. solution should be used only in exceptional cases, when the larynx is very tolerant, and presents deep fissures or crateriform ulcerations. The application is made by means of a cotton-wad under laryngoscopic guidance, and the contact with the lesion must be exact. In order to obtain quick tolerance on the part of the larynx it is well to precede the application of phenol sulforicinate by that of an aqueous solution of cocain. After a few applications the cocain may be omitted. There is said to be little nervous reaction. In a few cases slight spasm of the glottis may occur. Excellent results are reported in a large number of cases seen since 1889. Any recommendation made by one of sufficient experience and authority for the amelioration of an affection so painful and resistant as tuberculosis of the larynx deserves careful consideration; and from the evidence brought forward in this brochure we believe that Dr. Ruault has made a decided contribution to therapeutics. The tone of his writing is that of a careful and modest observer.

It is, therefore, deserving of attention, and his method should be put to extended trial by those having the opportunity to do so.

CORRESPONDENCE.

WHAT NEXT?

To the Editor of THE MEDICAL NEWS,

SIR: A new edition of a non-technical reference-book, *Johnson's Cyclopedia*, is at present being published, accompanied by much newspaper eulogy and a vast amount of advertising. It is notorious, of course, that the general public knows very little of technical questions, and general cyclopedias are intended for its enlightenment.

Turning to the word "Eclecticism" (vol. ii, p. 905), we find that "Dr. Robert S. Newton, of New York (1818–1881), first inculcated the doctrine of cellular pathology in 1845, and also introduced the antiseptic treatment in surgery in 1846. . . ."

Being under the foolish delusion that Virchow was the originator of cellular pathology, I looked up the eminent German scientist's name in the old edition (vol. iv, part 2, p. 1167), the letter "V" not being ready in the new issue. To my surprise I found these words: "He is the creator of the cellular theory in pathology" (1858).

Under "Lister" (new edition, vol. v, p. 295), the statement appears that Sir Joseph Lister is the founder of antiseptic surgery.

As I had never had the advantage of hearing of the existence of so eminent an investigator as Dr. Robert S. Newton, referred to by the writer of the article upon eclecticism, I looked for his name among the other illustrious Newtons, but found that, celebrated as he must have been, the editor of *Johnson's Cyclopedia* had omitted to insert his biography!

In the article upon "homeopathy" the assertion appears that "in Europe homeopathic physicians are not known as such. Many 'regular' physicians practise homeopathy."

The legal lore contained in this new reference-book, however, entirely eclipses the words of wisdom that appear under "homeopathy" and "eclecticism." The article upon "executor" informs the reader that "by the law of England an infant can act as executor after the age of seventeen." As this has not been the law of England for ninety-seven years (see 38 George III, Chapter 87, Section 6), one would suppose that the proprietors of the cyclopedia had had an opportunity of discovering that the common law had been altered.

Dr. Pepper, of Philadelphia, is the nominal editor of the medical department of the new Johnson; but nobody outside a lunatic asylum would suppose that the articles upon "eclecticism" and "homeopathy" appeared with his knowledge or consent. What editors are for, if not to edit, is a mystery that the Johnson Company might condescend to explain.

It is asserted that the well-known firm of Appleton is the real owner of the new cyclopedia, and one is, therefore, tempted to ask how it comes that so reputable a publishing-house permits a reference-work for the benefit of the general public to contain statements that have no foundation in fact. Respectfully,

LAWRENCE IRWELL.

76 W. TUPPER STREET, BUFFALO, N. Y.

NEWS ITEMS.

"*Fake*" *Hospitals.*—To control the establishment of so-called "fake" hospitals the following ordinance has been presented to the Councils of Chicago:

SECTION 1. That it shall be unlawful for any person, firm, association, or corporation other than the regularly constituted authorities of the State of Illinois, or the county of Cook, or the city of Chicago, to open, conduct, manage, or maintain any hospital as hereinafter defined, within the corporate limits of the city of Chicago, without first obtaining a permit therefor, to be issued by the Commissioner of Health of the city of Chicago upon the written application of such person, firm, association, or corporation, which application shall state the location or proposed location of such hospital, the purposes for which it is to be opened, conducted, or maintained, the accommodations or proposed accommodations for the inmates thereof, the nature and kind of treatment given or proposed to be given therein, and the name and address of the chief surgeon, physician, or intended chief physician or surgeon attendant thereat.

SEC. 2. It shall be the duty of the said Commissioner of Health, upon the presentation of such application, to make or cause to be made strict inquiry into the facts set out in such application, and if, upon such inquiry, he shall find that such hospital is or is intended to be constructed so as to afford proper accommodation for the care of the persons received or proposed to be received therein, and that the chief physician or surgeon, or intended chief physician or surgeon attendant thereat, gives or is under agreement to thereafter give such attendance thereat as does or will render him responsible professionally for the medical or surgical treatment given or to be given to any and all persons thereat, and that such chief physician or surgeon is regularly authorized to act as such under the laws of the State of Illinois, and upon the payment to said Commissioner of Health of a licence, permit, inspection, or examination fee of — dollars, he shall issue a permit in the name of the city of Chicago to such applicant to open, conduct, manage, or maintain a hospital at the place and in the manner and for the purpose in such application mentioned, which said permit shall cease and be operative the 31st day of December next following the issue thereof.

SEC. 3. It shall be the duty of such person, firm, association, or corporation, permitted as aforesaid to open, conduct, or maintain a hospital within the corporate limits of the city of Chicago, to make a report to the said Commissioner of Health on or before the fifth day of each calendar month, showing a complete record of such hospital during the preceding month, including the number of inmates received, discharged, and died during the month, causes of death, and such other information as may be necessary to an intelligent sanitary supervision of the establishment; such record to be furnished on blanks prepared and supplied by the Commissioner of Health, verified by the affidavits or affirmation of the chief physician or surgeon or superintendent attendant thereat.

SEC. 4. Every hospital permitted as aforesaid shall at all times be open to the inspection of the said Commissioner of Health or his duly appointed assistants or inspectors

Sec. 5. The Commissioner of Health of the city of Chicago is hereby authorized and empowered to inspect, or cause inspection to be made, whenever and as often as he may deem proper, of any hospital permitted as aforesaid within the corporate limits of the city of Chicago, and if, upon any such inspection, he shall find the same to be conducted, managed, or maintained in violation of the terms of the application for the permit under which the same was opened, conducted, managed, or maintained, or in violation of any of the health or sanitary ordinances, rules, or regulations of said city of Chicago, then and in that event he is hereby authorized and empowered to revoke any such licence issued for the opening, conduct, management, or maintenance of the same.

Sec. 6. Any person or persons, or corporation other than the regularly constituted authorities of the State of Illinois, county of Cook, or city of Chicago, opening, conducting, managing, or maintaining a hospital as hereinafter defined within the corporate limits of the city of Chicago without first having obtained a permit therefor as provided in Section 2 of this ordinance, or after a revocation of such permit under the authority conferred in Section 5 of this ordinance, or in violation of any of the provisions of this ordinance, shall be and is hereby declared to be guilty of maintaining a nuisance, and upon conviction thereof shall be fined in a sum not less than — dollars nor more than — dollars.

Sec. 7. For the purposes of this ordinance a hospital is hereby defined to mean any place or establishment used for the reception or care of the sick, injured, or dependent, including women awaiting confinement, or used for the medical or surgical treatment of mental or physical disease or injury.

Sec. 8. This ordinance shall take effect and be in force from and after its passage and due publication.

Bellevue Hospital.—The Commissioners of Public Charities and Correction of New York have lately asked the members of the Fourth Division of Bellevue Hospital to form an organization for the purpose of giving instruction to graduates and third-year students. The medical staff of the Fourth Division consists of Doctors C. L. Dana, George B. Fowler, and Alexander Lambert. The surgical staff consists of Doctors J. W. S. Gouley, Charles Phelps, and W. F. Fluhrer. The gynecologist is Dr. W. Gill Wylie.

The following communication from the Commissioners, and the answer thereto, are given for the information of the profession:

Department of Public Charities and Correction.
Commissioners' Office,

New York, September 3, 1895.

Gentlemen: I am directed to transmit the following proceedings of the Board at a meeting held this day:

Resolved, That the seven members of the Fourth Division of Bellevue Hospital be requested to form, without delay, an organization for practical instruction to graduates in medicine and third-year students in the hospital and the bureau of medical and surgical relief for outdoor poor.

Resolved, That the members of the Fourth Division shall be empowered to draw from the institutions subject to the division all necessary clinical material.

Resolved, That the Commissioners will heartily cooperate with the Fourth Division in carrying out the scheme of instruction.

Resolved, That certificates issued to those who shall have attended instruction, and signed by the seven members of the Fourth Division, shall be countersigned by the Commissioners, and shall bear the seal of Bellevue Hospital.

By order, G. F. Britton,
Secretary.

New York, September 6, 1895.

To the Commissioners of Public Charities and Correction.

Gentlemen: At a meeting of the Fourth Division of Bellevue Hospital, held on the fourth day of September, your communication was presented and read. The members of the division desire to express their high appreciation of the step you have taken, in the interests of the hospital and of the people at large, in thus adding to the usefulness of the vast amount of clinical material in Bellevue. They have, therefore, resolved to accept your invitation to become a teaching-corps, have formed the organization which you requested, and have further resolved to begin, on or about the 1st of October, the courses of instruction instituted by your honorable Board. Each course of instruction shall continue six weeks, and not less than five courses shall be given annually.

Very respectfully,
W. F. Fluhrer, M.D.,
Secretary.

The American Public Health Association will hold its twenty-third annual meeting at Denver, Col., October 1st, 2d, 3d, and 4th. The following topics have been selected for consideration:

The Pollution of Water-supplies; The Disposal of Garbage and Refuse; Animal Diseases and Animal Food; The Nomenclature of Diseases and Forms of Statistics; Protective Inoculations in Infectious Diseases; National Health-legislation; The Cause and Prevention of Diphtheria; Causes and Prevention of Infant-mortality; The Restriction and Prevention of Tuberculosis; Car-sanitation; The Prevention of the Spread of Yellow Fever; Steamship and Steamboat Sanitation; Transportation of the Dead; The Disposal of the Dead; The Abuse of Alcoholic Drinks from a Sanitary Standpoint.

The New Mexico Territorial Board of Health is to be commended for the publication for general distribution of circulars giving information as to the manner in which pulmonary tuberculosis is most commonly disseminated, together with directions as to the best means of preventing such dissemination.

Prof. Schede, of Hamburg, has been elected to the Chair of Surgery in the University of Bonn in succession to Prof. Trendelenburg.

Dr. John S. Bristowe, a distinguished English clinician, died on August 20th at the age of sixty-eight years.

OTITIS MEDIA AS A COMPLICATION OF PNEUMONIA.[1]

BY F. P. BALL, M.D.,
OF LOCK HAVEN, PA.

IT is the intention in this paper to call attention to otitis media as it occurs complicating pneumonia in children, and especially that form of pneumonia most common in childhood, broncho-pneumonia or catarrhal pneumonia. In fact, the three cases reported were all cases of otitis media complicating catarrhal pneumonia, and the very marked and decided cerebral symptoms, as will be seen, were entirely due to this complication.

Of course, otitis media often occurs as a complication of other diseases, and, in fact, quite recently I have seen it stated, of many other diseases, even including intestinal diseases. Indeed, it is not yet fully appreciated—or at least our knowledge does not yet go far enough to say—how many cases of what appears to be meningeal inflammation occurring in the course of other diseases is due to disturbance within the tympanic cavity. It is not fully appreciated because we have not been accustomed to search for and understand the effect of tympanic pressure upon the cerebral circulation. We have always understood and in some measure expected a complication of this character in a certain number of cases of the exanthematous diseases, as scarlatina, measles, etc., and have accounted for the cerebral disturbance in such cases by saying that there has been an extension of inflammation from the throat through the Eustachian tube and tympanic cavity to the meninges of the brain. While undoubtedly meningitis may and does thus arise, I think, in fact, many of the cases in which serious inflammation seems by all the symptoms we can appreciate to exist, the truth is that they are due to pressure within the tympanum, as in the cases hereinafter recorded.

While, then, we expect sometimes to meet with otitis media as a complication of diphtheria, scarlet fever, measles, etc., I think few have been accustomed to look upon pneumonia as one of the diseases likely to be attended with this complication. It is a complication quite frequently overlooked because the symptoms are referred to the brain instead of the tympanum, and the importance of it, too, is quite as often not appreciated. It is a complication recognized by various writers, it is true, and is a well-understood pathologic condition; but the references to it are so meager, and until recently the importance of the subject has failed of recognition except from the aural surgeons, who seldom see such cases as we are about to discuss, that it has not received the attention at the hands of the general practitioner that it should. That it occurs frequently, and that the symptoms induced by it are referred to some other cause, I am quite confident, and, in fact, as the cases here referred to will show, the symptoms of this complication are sometimes so misleading that unless we are very much on our guard it is an easy matter to suppose them to be due to some other pathologic condition.

The significance of otitis media has not only relation to the usefulness of a very important organ, the ear, but it has very profound bearing upon the life of the individual as well. Many a life has been jeopardized, and no doubt many a one also has been lost through a want of thorough appreciation of the importance of otitis media or a failure to discover its existence, or an inability to manage it properly when discovered. The effusion in the tympanum may, by pressure, so seriously interfere with the cerebral circulation as to cause death, or the pus there confined may burrow through the mastoid sinuses, producing mastoid disease, with all its serious consequences, or through the interstices in the thin lamella of bone lining the cavity, thus producing a true purulent meningitis. The danger to life being escaped, the danger to hearing still remains, and later-coming deafness is quite frequently traceable thereto. It is a question worth considering how many unfortunates might have been spared this calamity by early recognition and proper treatment of this complication of the various diseases that are its primary causes.

That otitis media may follow or complicate pneumonia, especially in children, as well as the exanthematous diseases, in which it is such a familiar accompaniment, it is the object of this paper to show. It is not at all the intention to consider this subject from the point of view of the aural surgeon, but to review the question of middle-ear disease as it should be recognized and treated by the general practitioner.

[1] Read before the West Branch Medical Association at Williamsport, Pa., January 29, 1895.

The following extract from the *Hospitals Tidende*, 1893, Nos. 18 and 20, reproduced in the *Therapeutic Gazette* of May 15, 1894, first called my attention to this matter and served to illuminate a case I then had under observation, and which had completely deceived myself and two consultants, our diagnosis being meningitis complicating pneumonia, whereas the lesion producing the cerebral disturbance proved subsequently to have been otitis media. Since then I have had two other cases, all of which shall be presently reported:

"A valuable communication is made by Rasch, of Copenhagen, of the results of sixty-one autopsies of children under two years of age. In but five cases was the tympanum normal, suppurative disease being present on one or both sides in forty-six, equalling seventy-five per cent., and catarrhal lesions in eight cases, or fourteen per cent. Nearly all of the children who had died of broncho-pneumonia showed otitis, and in thirty-three of the forty-three in which the secretion was rigidly examined the pneumococcus was present. Not a few of these children had shown symptoms leading to a diagnosis of meningitis, which was found absent on section, and the tympanic inflammation had been generally overlooked. Perforation of the drum-head was found but four times, and even when this occurs the condition is too frequently unrecognized or slighted.

"This is only a confirmation of what has been long urged and repeatedly demonstrated by otologists, but they too often are merely regarded as magnifying their office unreasonably. Numbers of such cases recover from the general disorder without recognition of the middle-ear disease, and give no evidence for a time that resolution has not been complete there; but the otologist finds a really normal drum-head a rarity, and must frequently trace later-coming deafness to such beginnings. This is the more deplorable when measures as simple as hot douching of the ear will often suffice to cure the disease in its early controllable stage; and a careful use of the Politzer inflation has at times instantly dispelled the symptoms of meningeal involvement, which delay might have made organic and irremediable."

The following cases, which came under my observation in the spring or early summer of the past year, illustrate the points brought out in the foregoing extract quite forcibly, and especially show how easy it is to mistake these cases for cases of meningitis, and also show, what is especially referred to in the extract, the close relation between the primary disease, pneumonia, and the complication otitis media:

CASE I.—A son of F. C. L., aged six years, had an attack of measles of mild character three weeks before the present illness and had apparently fully recovered. Just previously to this illness he had been exposed somewhat to cold and damp and had become overheated while preparing for some school-exercises at the end of the term. The first intimation that the parents had that the child was not well was that he seemed to have "taken a bad cold," and when I saw him on the second day of his illness he was suffering from bronchitis, though his most distressing symptoms were abdominal; indeed, there seemed to be a general catarrhal condition of the mucous membranes. There was considerable pain in the stomach and bowels, very decided tympanites, diarrhea, and occasional vomiting. The tongue was moist and covered with a white fur. The temperature was but slightly elevated and the pulse only 100. There were cough and some expectoration of tenacious, stringy mucus and subcrepitant râles, but no pain in the chest, and the percussion-note was clear over all parts of both lungs.

On the third day the abdominal symptoms were very decidedly ameliorated; the pain in the stomach and bowels ceased; the tympanites subsided; and the diarrhea stopped altogether, though there was still occasional vomiting. The temperature now rose to 102°, the cough became more distressing, and pain in the chest was complained of. Percussion detected a small area of dulness in the middle lobe of the right lung. On the fourth day the boy became quite restless, dull, and stupid, sleeping most of the time, throwing his hands about, and crying out as though in pain; he now complained of headache and rolled his head in the pillow, and, though in semi-coma most of the time, could be aroused by considerable effort, and would answer questions in monosyllables. Hearing was noticed to be quite dull in both ears, but much more markedly so in the left. When aroused, vision did not seem to be lost entirely, though it was evidently an effort for the child to concentrate his vision on any object. The pupils responded slowly to light and were sometimes dilated and again contracted, though never unequally contracted or dilated. The stupor became more and more pronounced as did also the deafness, so that it was hard to rouse the patient at all. His pulse became very rapid and feeble, though it was very difficult, indeed, to take it satisfactorily on account of his extreme restlessness; he was never quiet a minute, though apparently unconscious of his surroundings. The temperature, when it could be taken, remained at 101° or 102°, though I think if it could have been more accurately taken it would have shown a higher range.

At the end of a week sensation was so blunted that the cornea could be touched without any notice of it by the patient. During the time these cerebral symptoms were developing the chest-symptoms were subsiding. The pneumonia, which had extended to the greater part of the lobe affected, had commenced to clear, but on account of the head-symptoms the prognosis was exceedingly unfavorable. The boy was at this time seen in consultation by Drs. Armstrong and Lichtenthaler, and the diagnosis previously made of meningitis complicating broncho-pneumonia was confirmed, without a question of doubt arising in the minds of either consultant or myself. At this period of the disease I found it necessary to be absent from home for a few days and Dr. Lichtenthaler continued in care of the case for me, with a most serious prognosis from all who had seen the patient. Dr. Lichtenthaler saw him the next day and gives me the following history of the case during the time the child was under his observation. He saw the case

again on the following evening, but could detect no signs of improvement. On the next morning he found the boy decidedly comatose, lying flat on his back, with limbs outstretched, all delirium and irritability gone; the stupor was so profound that he could place his finger on the cornea over the pupil without eliciting any sign of consciousness whatever; urine was voided unconsciously in the bed; the temperature and pulse were about the same as they had been during the preceding days. He called to see the patient again in the evening, fully expecting to find him dead, but on entering the house he found everything changed. The patient, having almost entirely recovered from his condition of coma, would reply "yes" and "no" in answer to questions, and the doctor was informed by the mother of the child that "one ear had broken during the afternoon," and that in a short time the family had noticed the change for the better. The child had asked for milk, had also expressed a desire to urinate, and did so after being placed on the chamber; and had asked for bread and butter. The doctor removed considerable pus from the ear, and was informed that there had been quite a free discharge. From this time on there was continuous and certain progress toward recovery, with gradual decline in temperature and pulse-rate and restoration to consciousness, so that when I resumed charge of the case the temperature was normal, the mind clear, the memory good, and the deafness about gone.

CASE II.—A son of W. H. S., aged five years, had also had an attack of measles some two weeks previous to the present illness. When first taken sick his symptoms were those of a general catarrhal fever. The temperature the first two days ranged from 101° to 102°. The child had severe headache, vomiting, and diarrhea, more or less stupor, extreme restlessness, and some delirium. There was quite a troublesome cough also, which percussion and auscultation revealed to be bronchitic. On the second day the vomiting and diarrhea ceased, but the temperature rose in the evening to 103°, and quite perceptible deafness was manifest, which was, at that time, supposed to be due to quinin, which the patient had been taking. On the next morning (third day) the temperature rose to 104°, and percussion detected dulness over a small area of the right lung. The child slept most of the time and the deafness was extreme. He was restless and delirious for several days more, when the lung cleared up, the temperature fell, and deafness disappeared and he returned to full consciousness. There was no discharge from the ears in this case. A diagnosis was made quite early in the disease of the middle-ear disease complicating pneumonia, and this, in the light of subsequent events, I believe to have been correct.

CASE III occurred in a son of Charles S., aged six years. This case is but a repetition of the other two, and I do not think it will be necessary therefore to go into details in regard to it, as was done in the first case, in order to bring out the points to be considered. There is one difference, however, between Case I and Case III on the one hand and Case II on the other, viz.: In Case II there was no discharge from the ears, whereas in the other two there was, and in both of the former cases there was a rapid subsidence of the symptoms, with the appearance of the discharge, showing very plainly the relation of the brain-symptoms to the pus contained in the tympanum. In both cases the discharge was purulent, and I am very sorry a microscopic examination was not made to determine the presence or absence of pneumococci. In this case, as in the others, there had been an attack of measles, which had been apparently fully recovered from, and in some two or three weeks was followed by an attack of catarrhal pneumonia. Accompanying the pneumonia were the decided symptoms of brain-disturbance as though due to meningeal inflammation—the restlessness, headache, coma, fever, vomiting, and, in addition, the marked and very decided deafness. The coma in this case was, if possible, deeper than in either of the others, though there was not so much restlessness or delirium as in the first case. The bowels were constipated throughout and vomiting continued at intervals for four or five days. The deafness was so profound that it was almost impossible to make the child hear the loudest shout or to gain any intelligent recognition from him. This, however, was as much due to the deep coma as to the defect of hearing. The pupils responded to light, but sluggishly. The temperature on several occasions became quite high, on more than one occasion reaching 105.5°, and necessitating the administration of an antipyretic. The pulse was rapid throughout the illness. These very pronounced symptoms continued for eight days, at the end of which time there was a discharge from one ear, with a marked and rapid change for the better. By this time the pneumonic lung had cleared up, and after the discharge the temperature fell and the child rapidly convalesced.

A *résumé* of these cases develops several points quite forcibly, and I think they are of sufficient interest and importance to hold our attention for a few moments.

In the first place, we see the indisputable connection of the two conditions, the pneumonia and the otitis media, with its accompanying symptoms, so closely resembling meningeal inflammation that a differential diagnosis becomes an exceedingly difficult matter. Another point for consideration is the fact that while we have all the symptoms of meningeal inflammation, viz., the headache, vomiting, delirium, restlessness, fever, coma, and deafness, there is, in reality, no inflammatory action in the cerebral meninges at all. A member of the profession, whose opinion I value very highly, writes me concerning this point that "nearly everyone is agreed at the present time that in such cases it is simply an illustration of the fact that the infectious disease is influencing the brain as well as the lung;"

but if that means that the infectious disease, pneumonia, is producing a meningitis as well as a pneumonitis, I think the cases here reported, as well as the autopsies referred to in the extract already quoted, contradict that idea, for it will be remembered, in two of the cases referred to, the symptoms of meningitis subsided immediately on the relief of pressure by the liberation of the pus from the tympanic cavity, and in the other case the same thing, or practically the same thing, occurred probably by discharge through the Eustachian tube. It would seem quite evident, therefore, that in these cases the condition is not due to inflammation of the meninges, but is the result of pressure within the tympanic cavity upon the sinuses and veins, and that it is relieved instantly when the pressure is removed.

When this condition occurs as a complication of pneumonia or the various other diseases with which it is commonly associated, but especially pneumonia, it is quite an easy matter to overlook it, or rather to refer it to an entirely different pathologic condition; for, in the first place, it is a condition that it is acknowledged is not easy of diagnosis, and, secondly, the primary disease is very likely to obscure the lesion. In a recent paper by Dr. S. MacCuen Smith[1] attention is quite forcibly called to the facts just mentioned. This writer says that in the last three years he has seen six children die of middle-ear disease which was unrecognized until a few hours before death. "Four of the patients," he says, "were thought to be suffering from 'brain-fever' and two from 'meningitis,' and when we recall the perfect picture of meningeal inflammation presented by these cases we can readily understand how without the most careful examination of the case such errors in diagnosis occur." Gowers says in his work on *Nervous Diseases* that the pressure on the bloodvessels and sinuses in the tympanic cavity due to inflammatory action in the middle ear gives rise to symptoms that so closely resemble those of meningitis that the one condition is often mistaken for the other, and the diagnosis is almost, if not quite, impossible. Referring to the cases just reported, this difficulty of diagnosis is quite plainly illustrated, and the general appearance of the child, together with many minor details in each case, makes the difficulty still greater at the bedside.

There are some clinical features which assist at least in an approximate diagnosis. The pupils may be sometimes contracted and again dilated, but they are not unequally contracted or dilated. The deafness is likely to precede the coma, whereas the deafness, or rather the insensibility to sounds, in meningitis is in direct proportion to the depth of the stupor. I have never seen in these cases any retraction of the abdominal muscles such as occurs in meningitis, and while the bowels are usually constipated and there is considerable vomiting, still these symptoms are not so pronounced nor so constant as in meningitis. The pain that is complained of is usually referred to the ear or the side of the head, whereas in meningitis the patient simply complains of headache without referring to any special location of the pain. I have never seen the *tache rouge* in these cases, though I must confess I have also often seen it absent in cases of meningitis. An examination of the ear with a head-mirror and speculum is the most important and probably also the only certain method of making a diagnosis, and this assists very materially not only in the diagnosis, but also in the treatment of the case, which, as already said, is a very important matter.

Pathologically considered, the tympanic cavity is well arranged to act as a trap for any micro-organisms that may be in circulation in the respiratory apparatus or that may be forced into it by efforts at coughing, having easy communication with the throat by the Eustachian tube and being closed at its outer extremity by the tympanic membrane.

If we recall the anatomic structure of the cavity, we can readily see how inflammatory action in its interior may quite easily extend to the meninges of the brain or by pressure produce most serious and alarming symptoms. Many authoritative writers have called attention to the fact that most serious consequences result from pressure on the veins and sinuses of the meninges due to infiltration and exudation into the tympanic cavity, and when we remember that the cavity is only separated from the brain by a thin lamella of bone perforated by bloodvessels and frequently containing apertures, and that posteriorly there is a veritable and almost direct communication with the cranial cavity through the mastoid sinuses, it is not surprising that serious brain-disturbance, and even a fatal brain-lesion, should result from middle-ear disease. Indeed, it is surprising that serious results do not more frequently follow.

Inflammation of the middle ear occurs most frequently as a complication or sequel of some other disease, and is the result, as we say, of extension of inflammation, or perhaps, to speak more scientifically, of migration of bacteria from the throat or other outer parts of the respiratory system through the Eustachian tube to the tympanic cavity. This is quite a familiar complication of the exanthematous diseases, and quite recently I have seen several cases of tuberculosis in which the bacteria were probably forced into the middle ear, with consequent suppuration and purulent otorrhea, with loss of hearing—the same result, though due to different

[1] New York Medical Journal, July 21, 1894.

micro-organisms, that happened in the cases already referred to. It used to be a quite common complication of scarlet fever, and many a child suffered with an offensive discharge from the ear that made him obnoxious to himself and to others and finally lost the hearing of the ear or ears affected, if indeed he did not lose his life, before the discharge occurred, through this complication. I am glad to say that I seldom now see this complication of scarlet fever. Since the elucidation of the bacterial origin of these diseases and the adoption of the only rational method of treating the throat through antisepsis, I seldom see an invasion of the Eustachian tube by pathogenic bacteria. In all such cases it is my habit to pay most careful antiseptic attention to the throat, and I must say that as a consequence the absence of offensive otorrhea or deafness as a sequel has amply repaid for all the necessary trouble, which really amounts to nothing. As it is known that there may be invasion by the pathogenic bacteria of the tympanic cavity in pneumonia, tuberculosis, etc., as well as the exanthematous diseases, it seems to me it would be a wise precaution to use antiseptic throat-washes in these cases also, in order to prevent what might become a serious complication.

The prognosis in such cases as have been here reported and briefly discussed depends a good deal on the plan of treatment or on the success of the efforts of Nature at liberating the exudate confined within the tympanic cavity. If the pus is discharged, either by perforation of the drum or through the Eustachian tube, relief is speedy and recovery quite sure, unless this fortunate circumstance is too long delayed. If the pus is not liberated, death may result from the pressure on the cerebral vessels, or there may be burrowing of the pus, resulting in meningitis and death. Hot douching of the ear, inflations through the Eustachian tube, and at the proper time the liberation of pus by surgical means, are recommended as the proper method of treatment. The anticipation of the efforts of Nature by the surgical liberation of the pus gives much better prospects of recovery and much less danger of permanent loss of hearing.

PULMONARY TUBERCULOSIS—ITS EARLY DIAGNOSIS.[1]

By EDWARD F. WELLS, M.D.,
of Chicago.

The great practical importance of this subject must be recognized if only superficial consideration is given to a series of propositions the applicability of which will be conceded by every experienced physician:

[1] Read by title before the Detroit meeting of the Mississippi Valley Medical Association, Sept. 3–6, 1895.

a. Pulmonary tuberculosis is an affection that may be recognized in its early stages. The symptoms are clear, suggestive, distinctive; and detection of the signs amounts to a practical demonstration of its existence. If any doubts are present, they are speedily resolved by time and the development of the disease.

b. Diagnostic failures are not due to any inherent difficulties. On the contrary, they are usually due to remediable faults upon the part of the physician, as, for example, to a hazy conception of the clinical picture of early tuberculosis of the lungs; to obtaining an incomplete history of the case; to superficial physical examinations or to lack of facility in manipulation or interpretation in this field; and, finally, to a peculiar mental bias, which renders him loath to acknowledge the presence of that which he dislikes to discover.

c. The prevalence of pulmonary tuberculosis has diminished and is declining, and it is reasonable to believe that the extension of the malady may be further restricted by early impressing upon every patient the importance of those preventive measures that are everywhere recognized as being efficient.

d. Recovery from pulmonary tuberculosis occurs in a very considerable proportion of cases, and medical management plays an important rôle in bringing about this very desirable result. That early treatment is influential in curing the disease and prolonging life will not be controverted by any one familiar with the subject.

e. Pulmonary tuberculosis necessarily entails upon its victims months and years of invalidism, with probably radical modifications of personal, business, domestic, and social relations; together with the certainty of death, in the end, in the large majority of cases. Simple justice demands that patients be early apprised of these facts.

The diagnosis is based upon the history and phenomena presented by the individual case compared with the total blended knowledge that the observer has gained from his own experience and the published observations and opinions of others. Inasmuch as the first is an ever-varying and the second an illimitable quantity, it is clear that the limits of this short paper will permit consideration only of a few of the many important points that may be classed as peculiarly diagnostic. In making selections it will be my aim to call particular attention to those that I have oftenest seen neglected.

Without argument it will be taken for granted "that pulmonary tuberculosis is due to the lodgment and subsequent growth in the lungs of the bacillus tuberculosis; that the entrance of this microscopic organism is usually effected through the inspired air, and that the atmosphere becomes contaminated from the dried and pulverized sputa of those consumptives who carelessly expectorate

upon the ground, floors, articles of clothing, etc. And further, that in countries where the malady is prevalent all persons are, because of the reprehensible custom of careless expectoration alluded to, constantly exposed to the germs of the disease, and that all do not become affected is due to the short life of the bacillus, especially when exposed to sunlight; the lack of a suitable soil for its development, and the inherent and acquired immunity of individuals. It is nevertheless true that local pulmonary conditions, and acquired, and, especially, inherited constitutional peculiarities render the individual extraordinarily susceptible or non-resistant to the disease, and it is these contingents which furnish the great army of phthisical victims." It must be clear, from the foregoing statement of accepted facts, that a careful consideration of exposure, heredity, susceptibility, etc., is of the utmost importance in the study of doubtful cases.

Exposure is a phase of our subject that requires, and, no doubt, will well repay, further and elaborate investigation—statistical and experimental. Little is positively known—much is, probably correctly, surmised. We must say that the probabilities of a slight hacking cough being of tuberculous origin are increased if the patient is a resident of a densely populated community or is a member of a household in which there are cases of well-developed pulmonary tuberculosis, while they are lessened if the opportunities for inhaling the germs are meager, as, for example, in the resident of a sparsely settled community or the sailor returned from a long cruise.

Heredity is certainly of the utmost importance and demands the most careful inquiry in every case. Although it is probable that no one has seen a case of direct transmission of tuberculosis to the fetus, the reports of some observers to the contrary notwithstanding, yet it is well-nigh universally admitted that tuberculous patients transmit to their offspring a peculiar susceptibility to the disease, and the testimony of a great number of careful and creditable observers makes it certain that about one-half of all tuberculous patients belong to families in which other members have been similarly affected. That this inherited susceptibility is a most profound impression is attested by the demonstrable pertinacity with which it clings, generation after generation, to those families in which it has once obtained a foothold.

Susceptibility may be acquired in a variety of ways, some known, many unknown. Attention will only be called to the fact that the local pulmonary conditions attendant upon influenza, measles, bronchitis, and pleurisy render the patients more than ordinarily liable to tuberculosis.

In the early diagnosis of pulmonary tuberculosis a clear and full medical history is always of the utmost importance, although obtaining this is often a very difficult feat. Patients are not prone to make wilful misstatements, but some of the most suggestive of the early symptoms seem to them insignificant and unworthy of mention, or they may have escaped notice altogether. However, careful and direct questioning, especially in the presence of a close associate, will usually bring forth a fairly clear and it may be a graphic account of the access and early symptoms.

If we refer to the great wealth of accumulated literature upon pulmonary tuberculosis, we shall find the most disappointing uncertainties as to the mode of access; and, usually, particular attention is directed to the alleged fact that the mode of access is very varied. This I believe to be erroneous, and, as the result of a considerable experience, especially in private practice, I am prepared to maintain the position that a remarkable uniformity exists in the earliest symptomatology in cases of pulmonary tuberculosis.

The earliest symptom is usually a slight and unobtrusive cough, but having peculiar characteristics. It is of the variety known as "hacking," but often, if not generally, consists of a single effort. It is likely to occur only after a change of posture or after a deep inspiration. Deep breathing may cause the cough, but if the deep inspiration is repeated the cough is not reproduced. It is an infrequent cough, and may not be heard a half-dozen times in twenty-four hours. It is unaccompanied by expectoration. This cough may continue for a week, or for a month, when a change comes over the scene. The cough becomes more frequent, and there are several "hacks" with each effort, especially on rising in the morning, and perhaps on retiring at night, and after eating. Occasionally there is expectoration of a little mucus, which may be streaked with pinkish blood. At this time the patient may feel languid, complain somewhat of headache, have an impaired appetite, with a coated tongue and a tendency to constipation, and be conscious of being in a febrile condition. This exacerbation will be of a few days' duration, and may be so slight as to attract but little or no attention, or it may be so marked as to require the services of a physician, but this is unusual. A small or moderate hemoptysis may occur at this stage, independently of the mildness or severity of the other symptoms. At the termination of this febrile attack there is usually a slight purulent or mucopurulent expectoration, although this may escape notice. Attacks similar to the one described, but each more pronounced than the preceding, are likely to recur at intervals of from four to six weeks, but after the first one or two the local and general manifestations will have assumed such characters as to leave no doubt of their nature.

Without considering further these general features we shall pass to the diagnostic value of the individual symptoms of early tuberculosis.

The cough, after one or two febrile exacerbations, usually becomes more frequent. It is not completed with a single effort; is more open; is provoked by changes in posture, sudden exertion, deep breathing, laughter, etc.; may often be quickly reproduced by deep inspiration; and is accompanied by more or less mucopurulent expectoration, which is most abundant and most purulent in the morning upon rising. At this stage rarely, but at a later period oftener, the cough may be paroxysmal and occasionally accompanied by the vomiting of food after a meal. A cough of this kind is highly suggestive. The hollow cough, with heavy nummular expectoration, distinctive to even the laity, needs no extended mention. It will be understood, also, that in every case the expectoration should be submitted to microscopic examination. The discovery of the bacillus tuberculosis must be considered conclusive evidence of the existence of the disease under consideration, but the inability to discover this organism, even when many specimens are examined, cannot, in the early stages, consistently lead to a positive opinion in the opposite direction.

Hoarseness is a not uncommon early symptom, and recurrent attacks, which are not due to other easily discoverable causes, are highly significant of pulmonary tuberculosis. The hoarseness to which I refer is not due to laryngeal tuberculosis; is transitory and recurrent; has recognizable characteristics that are peculiar, and occurs in a pretty large proportion of cases.

Hemoptysis is a symptom of the greatest diagnostic importance. It occurs in only a moderate proportion of the cases of early pulmonary tuberculosis, but it is very significant when it does appear. As a matter of fact, an hemoptysis preceded by a period of cough is, practically, pathognomonic of tubercles in the lungs. It is true that there may be spitting of blood from spongy gums, from hemorrhage from the posterior nares, throat, etc., but, clinically, these cases are easily properly classified. The hemoptysis may be small, moderate, or profuse; transitory, more or less persistent or recurrent; but it is usually small or moderate and solitary, or mildly persistent for several hours, although it is not infrequently recurrent. It is seldom very profuse, although it may be in rare cases so profuse and persistent as to destroy life. Although cough is almost always the initial symptom, and the patient may have had one, with slight expectoration, for several weeks or months, together with one or more febrile attacks, yet the fact remains that in a considerable number of cases hemoptysis is the first symptom that excites the alarm of patients and their friends and that leads to a consultation with the physician. In such cases only the closest questioning will correct the error of observation.

Thoracic soreness and pain occur early in most cases of pulmonary tuberculosis. The pain may be a sharp, evanescent stitch, recurring at irregular intervals, with long periods of absence; it may be less acute and continuous for several hours or a day or two; or it may be a sense of soreness, noticeable with inspiration, especially deep inspiration, and it may be attended with tenderness upon pressure. The favorite location for these pains is the region round about a point midway between the nipple and the clavicle. They may be axillary, supraclavicular, suprascapular, or even basic, although the last is uncommon. The location is often indefinite, as is also the character, but this very indefiniteness in character and location is in itself a suspicious symptom.

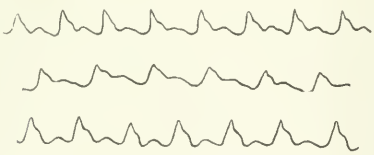
The early febrile attacks are usually accompanied by gastric and intestinal disturbances. The tongue is coated, the appetite is impaired, and the bowels are constipated. Excretion generally is deficient, and the condition is often classed as a bilious attack. Subsequently the appetite is likely to be erratic and somewhat impaired, while the powers of digestion and assimilation are diminished. In some rather infrequent cases there is present a veritable dyspepsia of tuberculosis, and in other rare cases there may be, in the early stages, no impairment whatever of the appetite, of digestion, or of the assimilative powers.

Nutrition, corporeal weight, strength, and endurance are early diminished. The patient may have a ruddy countenance and the general appearance of health, but an appeal to the scales will show a loss of weight, and it will be found that in the exercise of strength there is an inability to duplicate records, and feats that were formerly accomplished with ease are only possible with difficulty and with added exertion. Endurance is markedly impaired. The patient tires easily and unaccountably. This symptom is one that early attracts the patient's notice, although it may require pointed questioning to obtain the information.

The thermometry of early tuberculosis is deserving of very careful attention. Frequent observations of the corporeal temperature for several days will clear up many a doubtful case. During the febrile attacks to which I have referred the temperature usually ranges from normal to 100° F. in the morning to between 100° F. and 103° F. in the evening. At these times, however, more frequent observations should be made, and it will often be found that the highest temperature occurs in the late afternoon rather than in the evening. At other times the temperature is usually slightly elevated during the late afternoon and evening. In a patient with a slight cough the regular elevation of the

body-heat from one-half to one-and-one-half degrees is very significant. An evening elevation of temperature may occur in some other diseases, *e. g.*, in anemia, obscure suppuration, etc. ; but these are usually readily eliminated from the diagnostic field. In some cases the patient may be free from fever in the interim between the exacerbations, but this is uncommon.

A study of the pulse will afford some of the earliest indications of the existence of pulmonary tuberculosis. From the start the characteristics of the pulse are changed from the normal. Usually the pulse is accelerated, and the rate is modified very little by position. The latter feature is very suggestive, and whenever the pulse-rate is found to be practically the same, whether the patient be lying, sitting, or standing, the most careful scrutiny is demanded. To the finger the pulse may be described as being "hurried," irrespective of its rate, although the rate is usually notably increased—ranging from 75 to 100 per minute. In some cases in the early stages the rate may not be perceptibly accelerated, and in others the frequency of the pulse may be very great, *e. g.*, 120, 140, or 160 per minute, but such cases are rare. It is, however, from sphygmographic tracings that we obtain the most valuable aid from the pulse in the diagnosis of early pulmonary tuberculosis. From this alone, in the great majority of cases, may be confidently predicated the presence or absence of tuberculosis in a doubtful case. Typical examples of tracings from cases of early tuberculosis are here introduced :



There are two classes of cases in which the question of differential diagnosis may arise in which the sphygmographic tracings afford no assistance. These are early typhoid fever and febrile attacks generally in some of those persons who are recognized as being hereditarily predisposed to pulmonary tuberculosis. These conclusions are derived from some studies in sphygmography upon which I am now engaged and which will soon be published.

The importance of a careful physical examination of the thorax needs no extended mention. The flattened chest will at once attract attention and be given its due weight in summing up the probabilities. It must be remembered, however, that although ill-formed, abnormal chests appear with frequency, yet well-shaped and symmetric thoraces are encountered in the majority of cases of tuberculosis. There will be usually found in the earliest stages a respiratory capacity below the normal, and a narrow range of the thoracic excursions, unless the patient has previously practised deep breathing. In many, if not in most cases, the respiratory movements at the upper portion of the chest, on one or both sides, are manifestly diminished. In practising percussion preference should be given to the method known as "stethoscopic percussion," because in this manner the extent and degree of any consolidated patches of lung-tissue may be detected with greater certainty than by the ordinary method, and it is possible to detect and locate small areas that would otherwise remain undiscovered. During the febrile attacks more or less extensive areas of dulness may be found which did not previously exist, and these disappear with the decline of temperature. This is due, as is well known, to pulmonary inflammation in the vicinity of the tuberculous deposits, and is very characteristic. It will be borne in mind that any dulness at the apex is highly suggestive of pulmonary tuberculosis, but the converse does not hold good, as there may be present a deposit of tubercle with no perceptible impairment of the percussion-note. In practising auscultation it must be remembered that there is, normally, a difference in the respiratory sounds of the apices of the two lungs—those of the right being loudest and roughest. During the febrile exacerbations there will be found but little difficulty in detecting the abnormal sounds characteristic of early tuberculosis ; but at other times much care, skill, and tact may be required in their recognition. It is scarcely possible to overestimate the diagnostic importance of localized crepitation, of rough or rasping inspiration below the clavicle, and of whistling or tubular expiration. Less distinctive, yet of suggestive significance, are the wavy infraclavicular inspiration and the weak respiratory sounds of the extreme apex.

In conclusion I will say: Satisfactory diagnoses in cases of early pulmonary tuberculosis are to be made only upon a broad base of practical knowledge. It must be apparent that it is impossible to compress within a short paper and a few minutes more than a modicum of that which many volumes cannot embody nor years attain. It is believed, however, that sufficient has been presented to prove that the early diagnosis of the affection under consideration presents no insurmountable difficulties, and that the exercise of a reasonable amount of care and skill, and in a few cases the lapse of a little time, will almost invariably lead to correct conclusions. In attaining these results no portion of our knowledge concerning pulmonary tuberculosis should be neglected, but particular attention may well be given the points mentioned, the most important of which are the following :

1. Preliminary history, including heredity, exposure, and susceptibility.

2. Medical history, including the mode of access and subsequent course.

3. Symptomatology, including the character and significance of the cough and expectoration; hoarseness; hemoptysis; pain and soreness; gastric disturbances; nutrition, weight, and strength; temperature; pulse and sphygmography; thoracic inspection and mensuration; percussion and auscultation; examination of sputum, etc.

34 Washington Street

GENU VALGUM; WITH OBSERVATIONS ON CORRECTIVE OSTEOTOMY.[1]

By SCHUYLER C. GRAVES, M.D.,
of Grand Rapids, Mich.;
Consulting Surgeon to the U. B. A. Hospital and Surgeon to the Children's Home.

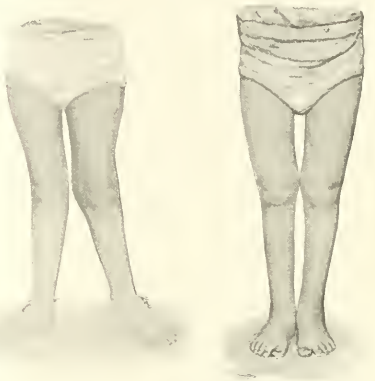
When the knee lies internal to a line drawn from the acetabulum to a point on the dorsum of the foot, midway between the malleoli, a condition of *genu valgum* or knock-knee is said to exist. It is only, however, to aggravated deviations from this rule that the term can be surgically, and hence properly, applied, because moderate degrees of the deformity are normal to the human creature; that is to say, the center of the knee will normally be found on the inside of the line just mentioned. This is due to the fact that the axis of the thigh, on account of the length of the transverse pelvic diameter, does not coincide with that of the leg, but intersects it at an external obtuse angle of large degree, thus throwing the knee to the inner side of the acetabulo-malleolar line. This state of affairs is much more pronounced in the female than in the male, because of the greater pelvic width in the former, thus rendering still less coincident the femoral and crural axes. Such divergence in axial trend must be harmonized by some mechanic factor at the point of articular contact, and this correction is brought about by an elongation of the internal femoral condyle, which is from one-quarter to one-half inch longer than its fellow.

Statistics show that *genu valgum*, in relation to general surgical diseases and malformations, bears the ratio of about one to twenty-four, and to its congener, *genu varum* or bowlegs, of a little more than one to two, bow-legs being observed a trifle less than twice as frequently as knock-knee. The deformity may be unilateral, bilateral, or mixed, being in the latter instance associated with bow-leg in the opposite member; and when bilateral it may present different degrees of variation in the two limbs.

[1] A paper read before the Northern Tri-State Medical Association, at Coldwater, Michigan, July 9, 1895.

Genu valgum has been noticed in the newborn; but it usually does not appear until the child commences to stand or to walk, and the cause is almost always rachitis. As stated by Young,[1] "Rickets softens the bones, weakens the muscles and ligaments, and the superincumbent weight of the body accomplishes the rest." Other elements enter into the etiology of this condition, such as inflammations, with or without trauma; displacing fractures; paralyses, as the result of nutritional disturbances; the postural factor in occupations, etc., but the disease called rickets must always remain as the most frequent cause.

Fig. 1. Fig. 2.



May 7, 1894.—Genu valgum.—August 7, 1894.

The pathology of *genu valgum* includes primary softening, with secondary hardening of the osseous structures; linear hypertrophy of the internal condyle, together with atrophy of the external; stretching and weakening of the internal lateral ligament, with corresponding contraction and condensation of its fellow, externally; muscular changes on account of position or disease, and greater or less rotation and antero-posterior curvature both above and below the joint.

The symptoms, signs, and hence the diagnosis of this deformity are readily recognized, the naked-eye appearances being amply sufficient. The following are a few points bearing upon this part of the subject: The feet are more or less widely separated and everted when the limbs are extended and the knees are in contact; there is impossibility of approximating the feet when the limbs are in the position just described, together with excessive lateral joint-mobility, disappearance of the deformity on flexion of the legs upon the flexed thighs, supposed

[1] Orthopedic Surgery, page 292.

to be due to lack of antero-posterior thickening of the internal condyle, etc.

In the matter of prognosis it has been stated by some writers that time is corrective; but I doubt if any well-authenticated case of formerly pronounced and latterly "out-grown" *genu valgum* can be exhibited. Recovery by the operation of time, that is, by natural growth and the action of better-toned muscles, except in the mildest types, is not to be expected. Deformity may not increase, certainly *will not* increase after the osseous eburnation that frequently follows rickets; but active mechanic interference must be instituted if we desire to do our patients any substantial good.

This brings us to the most important and, at the same time, the most interesting portion of this subject, the treatment. Naturally the matter falls under two heads, viz.: First, non-operative; second, operative. Under the first we note such manipulative factors as massage and pressure, the latter exerting its force in a direction, of course, away from the central axis of the body, while the extremities of the limb are fixed. This pressure can be applied either by the hand of the masseur or by properly constructed apparatus, to be worn indefinitely, but taken off when the patient is in bed.

This apparatus-treatment is, in my opinion, a relic of barbarism, and ought to be relegated to the companionship of its fellows in the dusty garret of surgical crudities. It may be possessed of some usefulness, though never necessary, while the bones are yet soft and more or less elastic; but after the advent of sclerosis its employment, in view of the better means obtainable, is, of course, absurd. It is a slow, clumsy, often ineffective, discouraging, and torturing method.

The way to correct a case of *genu valgum* to-day is to resort to either osteoclasis or aseptic osteotomy. By the former is meant the securing, through any well-directed force, of a simple fracture of the femur at or near the proper point. This method is inexact, and, although it furnishes the great desideratum of securing correction without the necessity of compound fracturing, has not been extensively adopted by operators. The *noli me tangere* in the surgery of the past is no longer the bugbear of the present, and when micro-organic life is not introduced into his wounds by the surgeon or by others—that is, in the absence of contact-infection, he may be certain of kindly results in his cutting-operations. I confess I am partial to osteotomy for the correction of curvatures of the long bones, and, through my experience, I have reason to be so.

Several excellent operations have been instituted within the past twenty years for the correction of *genu valgum* by osteotomy, although deliberate osteal sections for the same purpose were undertaken long ago, the first having been performed by Meyer, of Würzburg, in 1851. The best of these operations are the following three: 1. Ogston's; 2. Macewen's; 3. MacCormac's.

The first consists in separating the internal condyle from the shaft of the bone by a vertical section, and, after sliding the condyle up the diaphysis a sufficient distance, fastening it there. This procedure, however well it may correct the deformity, is never justifiable, in view of the fact that the great knee-joint is unnecessarily entered; for other operative methods fully as efficacious avoid, and very justly, the penetration of this important articulation. Hence, the Ogston method will be discussed no further in this paper.

The remaining two operations, viz., the Macewen and the MacCormac, are the ones I propose considering. Although the former is the product of a mighty mind and is recommended to-day by almost, if not quite, all of the text-books as superior to the MacCormac, it is, in my opinion, inferior to the latter, or rather to the modified MacCormac, as I shall proceed to show.

In the Macewen operation the incision is made vertically on the *inner* aspect of the thigh, and the bone divided "at a point where the two following lines meet; one drawn transversely, a finger's breadth above the external condyle, and a longitudinal one drawn one-half an inch in front of the adductor magnus tendon." In the MacCormac operation the incision is made transversely on the *outer* aspect of the thigh at a point about two inches above the lower femoral epiphysis.

In an osteotomy for *genu valgum* on a boy of five that I performed a year ago the MacCormac operation with some original modifications was chosen. These modifications were the following: 1. A change of incision from the transverse to the vertical direction; and 2, an incomplete section of the bone, with the production of a "green-stick" fracture in the portion undivided.

First. The MacCormac incision is transverse, and can only be accounted for on the ground of permitting better vision during the procedure. A surgeon, in the first place, should see with his fingers, and, in the second place, he should make incisions that disturb to the least possible extent consistent with thorough work the normal anatomic relations of the structures through which he needs must pass. A transverse incision in this operation divides the fibers of the vastus externus; a vertical one simply separates them. Union after transverse section of striated muscle is practically never followed by restoration of purely muscular continuity. Fibrous tissue takes the place of the destroyed muscle-cells, and a plane of connective tissue subsequently appears at the site of the former incision, thus damaging, in direct proportion to the amount of connective tissue present, the contractility and hence

the usefulness of the muscle. It is needless to say that longitudinal separation of the muscle-fibers, when permissible, is better surgery than transverse section.

Second. In no text-book or operator's work have I seen advocated the securing of a "green-stick" fracture as a factor in the correction of *genu valgum* or *varum*. It is, of course, possible only in the young; but children form and will continue to form the great majority of cases for operation. "Green-stick" fracturing is impossible in the Macewen operation, because the *inner* portion of the femur is at once divided. In the MacCormac operation, however, the *outer* portion being the first to undergo division, the remainder, after gentle testing, may be subjected to pressure sufficient to fracture incompletely, and thus permit of deformity-correction without total loss of osseous continuity. This can generally be effected, though not always, and, as can readily be seen, is a great advantage over complete bony section. I at once noticed the value of the MacCormac site in relation to this operative feature.

In the performance of these osteotomies, after placing the limb on a sand-bag, the desired section of the bone is readily accomplished by the free use of the mallet and chisel, and at the same time the correction is made and a plaster-cast applied over proper aseptic dressings, and allowed to remain for from two to three weeks without disturbance.

When one limb is deformed to a greater degree than its fellow, if the variation be not pronounced, a compensatory tilting of the pelvis will overcome the moderate difference in the length of the limbs caused by correction; but when this variation is considerable a sufficiently long, cylindric section of the femur in the limb that shows the greater deformity must be removed in order to render the limbs of equal length.

To the Macewen operation I find the following objections:

1. It has to be performed in the neighborhood of a greater number of important structures than is necessary, viz.: The internal saphenous vein and nerve, the anastomotica magna artery, and to a certain extent the internal, upward prolongation of the synovial membrane lining the knee-joint, in regard to which Gray[1] states: "On each side of the patella the synovial membrane extends beneath the aponeurosis of the vasti muscles, and more especially beneath that of the vastus internus." 2. The line of section is, for obvious reasons, too close to the epiphysis. 3. It necessitates the cutting of a wider expanse of bone than is desirable. 4. It precludes the possibility of an advantageous "green-stick" fracturing.

The following points of superiority attach to the modified operation of MacCormac:

1. The incision *separates* the muscular fasciculi, and does not appreciably *divide* them. (This condition of affairs I know obtains in the Macewen operation, and, therefore, the latter is not inferior to the former in this respect, but the innovation is an improvement on the old MacCormac.)

2. The only important structure to be avoided, with the exception of the popliteal artery, which, by the way, should be borne in mind during *any* osteotomy for the remedy of this deformity, is the peroneal nerve lying in close proximity to the tendon of the biceps; but this chord, by virtue of the trend of the incision, is in very little danger.

3. The operation permits of partial, external bone-section with a maintenance of internal, osseous continuity.

In conclusion allow me to recapitulate the modifications of the MacCormac operation that seem to possess merit:

1. The employment of the longitudinal instead of the transverse incision. 2. The aim to secure correction of the deformity without total loss of osseous continuity, through the agency of the so-called "green-stick" fracture.

The former modification is an exemplar of neater and hence better surgery, and the latter not only renders the MacCormac method the preferable one in the majority of instances, but also, by greater ease of manipulation and by greater certainty of good results, changes the dictum of many authorities as to the treatment of cases in which such procedure is possible, viz., the children afflicted with this distressing deformity; for, while heretofore it has seemed best to defer operations on the young and to try the effect of corrective apparatus, it can now be stated as a recognized fact that in these same boys and girls, who have all the time imaginable at their disposal, and in whom center all the possibilities associated with the training and molding of structures actively engaged in the processes of evolution, is found every indication for the performance of one of the most humane as well as one of the most brilliant operations in the realm of modern aseptic surgery.

VULVOVAGINAL ANUS, WITH REPORT OF A CASE.[1]

BY LEONARD FREEMAN, B.S., M.D.,
OF DENVER, COL.;
PROFESSOR OF THE PRINCIPLES OF SURGERY AND SURGICAL PATHOLOGY, GROSS MEDICAL COLLEGE; PATHOLOGIST TO THE COUNTY HOSPITAL, DENVER.

CONGENITAL malformations of the rectum and anus are of rare occurrence, but they are of so much importance to the future welfare of an infant, both physically and mentally, that they deserve earnest attention. Operative interference is often success-

[1] Read before the Golden Belt Medical Society of Kansas, July, 1895.

ful, and should be attempted in every case, no matter how small the chance of affording relief may be; for in the bad cases it is better that the little patient should perish in an attempt to remove the affliction than to carry so objectionable a deformity through life; and, besides, many cases would rapidly succumb if not promptly operated upon.

Malformations of the rectum and anus may be divided into four principal kinds:

1. *Atresia ani*, in which the anus alone may be absent, or the entire lower portion of the bowel as far as the upper border of the internal sphincter. Sometimes a small fistulous opening remains, which is usually situated further forward in the perineum than normal. A dimple often marks the spot where the anus should exist, and the fibers of the external sphincter may be present beneath the skin.

2. *Atresia ani et intestini recti*, in which the colon ends in a blind pouch at the level of the last lumbar vertebra, or on the left side at the upper border of the sacrum.

3. *Atresia recti*, in which the rectum ends at some portion of its course without communicating with the anal portion of the bowel. The latter, however, is present, projecting upward from the anus like a short glove-finger. In rare cases the rectal pouch may open into the vagina.

4. *Cloaca congenita*, in which the rectal pouch, lying generally in the hollow of the sacrum, opens into some portion of the genital or urinary tract. The opening is often small, and may lead into the rectum through a narrow canal. In the male sex the opening may be into the lower portion of the bladder, or into any part of the urethra; while in females it is often into the vagina, generally into the vulva near the posterior commissure (vulvovaginal anus). Very rarely the rectum communicates with the uterus. When the opening is in the upper part of the vagina the latter is often double, the feces passing through but one of the divisions.

The ileum or jejunum may end in a *cul-de-sac*, or present more or less of a stricture at any point; or the small intestine may open at the navel or in the inguinal region. Dinsmore observed a case in which the opening was on the shoulder.

In order properly to understand these various malformations it is necessary to study the method of formation of the rectum in the fetus. The rectal and anal portions of the bowel are not formed in a continuous tube, as one would naturally imagine, but exist as separate structures, which gradually approach each other and finally unite about the fourth week. In other words, the rectum ends at first in a blind pouch, while the anal portion begins in a puckering of the surface, which slowly deepens, as though the skin were being pushed inward by the end of a finger, until it unites with the rectal pouch above.

Another important point is that at this stage of development the genital and urinary tracts open into the rectal pouch, so that the anus becomes a cloacal opening such as exists in birds. Just how it occurs we do not know, but certain disturbances in intra-uterine life may check the proper development of the parts at any period. The anal portion of the bowel may not form at all, or may fail to unite with the rectal portion above; or an abnormal opening of the rectum into one of the urinary or sexual organs may result.

These accidents of development seem to appear more frequently in certain districts and in certain families. Wurtzer mentions a family in which out of ten children three were afflicted with occlusion of the rectum, while König observed the deformity in a father and two sons. When such an occlusion exists, the infant usually promptly dies unless relief is afforded by operation, but this is not always so. Bartholin saw a man forty-two years old in whom the feces were periodically evacuated through the mouth, the intestine having doubled on itself and opened near the upper end of the esophagus. Baux observed a girl of fourteen years who evacuated the contents of the bowel through her mouth every two or three days. A similar case was seen by Denys.

In the present paper I shall consider the vulvovaginal anus only. Approximately between 60 and 100 cases have been reported. The opening is always in the posterior wall and generally low down near the posterior commissure. When it is high up there is often a double vagina, the bowel communicating with only one side. The opening may be small or large, and it is usually so guarded by a sphincter muscle that fecal matter is perfectly retained, although incontinence sometimes exists. The deformity is often not at all incompatible with longevity or even with a certain amount of physical comfort. Morgagni mentions a Jewess thus afflicted who lived to be over one-hundred years of age. Ricord cites a case in a woman of twenty-two years whose husband during the course of three years discovered nothing abnormal in her condition. Dwight reports a case in a woman of thirty-two years, Deutsch one in a woman of twenty-nine years, and Tuck one in a woman of twenty-six years.

The bowel nearly always runs parallel with the perineum almost to the coccyx before it turns upward, and there is often a depression of the skin where the anus ought to be. A normal anus may also be present, and the vulvovaginal opening may be closed by a membrane or by a valvular fold of mucous membrane, so that no fecal matter enters the vagina. In fact, cases have been recorded in which the deformity has not been observed until after marriage, when the opening has been accidentally rendered patulous. In one instance the wife believed

herself to have been injured by undue violence in coitus, and medico-legal complications resulted.

When the right operation is properly performed the best results are often obtained; otherwise more harm may be done than good. Curling has collected 100 cases of malformation of the rectum, including eleven cases of vulvovaginal anus. Operative interference was successful in ten of the latter, only one resulting fatally. But, in spite of a successful operation as such, failure may sometimes result from other congenital complications. It is not necessary, and often not desirable, to operate at once upon cases of vulvovaginal anus, if the opening is sufficiently large to permit defecation. Very young babies may not withstand an operation as well as somewhat older children, and the condition is often such that delay is not at all dangerous.

Some operators prefer to open the bowel in the anal region near the coccyx by a simple longitudinal perineal incision, suturing the cut edges of the gut to the skin, and closing the vaginal opening either at once or subsequently. This is not a commendable method. As is well known, it is not always an easy matter to close a rectovaginal fistula, and, in addition, the proper anal sphincters may not be retained.

Another method of operation is to split the entire perineum and bowel from the vaginal opening back to the normal position of the anus, throwing the lower portion of the vagina and the anus into one, and leaving the repair of the vagina and perineum to a future operation. But this is a bungling procedure at the best, which may lead to prolapse of the vagina or uterus, in addition to a long period of treatment and an imperfect functional result.

Taking all things into consideration, the method of Rizzoli, which I employed in the case to be described, gives the best results, enabling the operator to restore at once the normal condition of the parts at a single operation. The internal sphincter, with its nervous mechanism, is retained, so that the anus can immediately perform its proper function, only temporary incontinence, or perhaps none at all, resulting.

The case I desire to report in this connection was that of a twelve-months-old baby, well developed and well nourished, having an anal opening in the posterior wall of the vagina just within the vulva. The opening was about the size of a wheat-straw, and was so provided with a sphincter that no incontinence of feces was present. A small dimple marked the spot where the normal anus should exist. There was no evident hymen.

Under chloroform-anesthesia a longitudinal incision was made in the perineum from near the tip of the coccyx almost to the posterior vulval commissure. A sound was inserted into the bowel through the vaginal anus to serve as a guide, and the perineal incision was gradually deepened until the rectum was reached. This was then loosened in its entire circumference from the surrounding tissues, including the posterior vaginal wall, by means of blunt instruments, and careful snipping with a pair of blunt-pointed scissors. The end of the bowel was then cut out from the posterior wall of the vagina with a pair of fine scissors, leaving an opening slightly larger than the original anus. This opening was at once closed by fine sutures. The entire bowel, including the vaginal anus, which I slightly enlarged, was then swung backward through the perineal incision to its normal position in front of the coccyx, and the edges of its orifice united by a number of silk sutures to the cut edges of the skin. A few deep stitches served to unite the perineum in front, thus restoring the parts to the condition in which they appear in a normal child. The anus, however, was left rather larger than natural in order to allow for subsequent contraction, although the method of suturing the mucosa to the skin prevents this in great measure.

The sutures were removed on the eighth day, and the child was sent home on the tenth. The anus functionated perfectly from the first, no incontinence being present at any time. This was owing to the fact that the internal sphincter, with its nervous connections, had been preserved.

I heard from the case four months after the operation. The bowel was then performing its functions in a normal and satisfactory manner.

CLINICAL MEMORANDA.

UNUSUAL APPEARANCE OF A CIRCINATE RINGWORM.

BY J. ABBOTT CANTRELL, M.D.,
OF PHILADELPHIA;
PROFESSOR OF DISEASES OF THE SKIN IN THE PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE; DERMATOLOGIST TO THE PHILADELPHIA HOSPITAL AND TO THE SOUTHERN DISPENSARY.

THE appearances witnessed in a case of ordinary superficial ringworm that presented itself at my clinical service at the Philadelphia Polyclinic were so unusual that a brief description and illustration may not be without interest. The case in question occurred in a girl about ten years of age, and the lesion was situated upon the right forearm slightly below the elbow on its outer aspect. The outer and larger ring of the eruption was found to have a diameter of one-and-three-quarters inches and to be perfectly round, having a number of vesicles around the borders of the lesion. This portion of the diseased area did not present anything unusual, but it was the condition that was witnessed in the center of this ring that was the most interesting part of the appearance. Within this larger ring were found five smaller lesions which were arranged in the following manner: They occupied the center of the larger lesion, and ranged from one-eighth to one-half of an inch in diameter. Although these latter lesions were separate in themselves, they were closely packed together and to some extent resembled the appearances witnessed in a clover-leaf. The outer or larger lesion was somewhat older than those included within its circle, the smaller

ones being only of two days' duration, while the older one was of about two weeks' existence.

The accompanying drawing with the microscopic report is the work of my assistant, Dr. Jay F. Schamberg. The scales were immersed in a 20 per cent. solution of potassic hydroxid, and examined with a Zeiss one-twelfth oil-immersion lens. The scales from the larger or outer ring showed abundant mycelia of varying size—some short and broad, others long and thread-like.

There seemed to be rapid fructification, as evidenced by the prolific arborescent bifurcation. Spores were almost entirely absent. The scales from the inner circles showed much less abundant fungus. The mycelia were for the greater part long and narrow.

In looking over the literature of the subject of this form of vegetable parasitic affection I am unable to find any reference to a similar arrangement of the lesions, but it has been my fortune to have recorded[1] recently another unusual arrangement in which the patch was made up of two rings that were concentric and not connected the one with the other.

315 SOUTH EIGHTEENTH STREET.

ANTECEDENT ORCHITIS IN A CASE OF MUMPS.

BY W. F. MARTIN, M.D.,
OF COLORADO SPRINGS, COL.

ABOUT three years ago a man of thirty-two years, the father of one child, three years of age, presented himself at my office, and complained of pain and tenderness in the left testicle. This, on examination, was found distinctly swollen and tender, the swelling being almost entirely confined to the testicle proper. There was also slight feverishness. There was no urethral discharge, and no evidence or history of any local cause to account for the condition; further, the man himself denied sexual intercourse with any one for the preceding two weeks, his wife having had an unusually prolonged menstruation, from which she was just recovering. The treatment advised was local rest for the parts and the free application of iodoform-ointment. The next day I was requested to see the man at his house and found him in bed, with a temperature of nearly 104°, a quickened pulse, and marked prostration. The testicle was still further enlarged and very tender, being fully twice the size of the opposite organ. On the left side of his face (the same side as the inflamed testicle), involving the parotid region, was a pronounced swelling, unmistakably the parotid gland itself. The patient complained of some discomfort due to the tension caused by the swelling, and of some trouble in mastication, but otherwise his attention was concentrated on his swollen testicle.

The succeeding history is, briefly, that of a steady and gradual decline of the testicular and the parotid swellings and of the fever, so that in a week the patient was entirely well. Three months later the affected testicle was found atrophied and soft, being about one-half its normal size.

This then seems without question to have been a case of so-called metastatic testicular inflammation of mumps, *preceding* the appearance of the parotid manifestation, and, if any deductions may be made from a single case, it would seem that such an antecedent involvement of the testicle would presage a severe attack of parotiditis.

In the literature at my disposal I have failed to note any reference to inflammation of the testicle preceding inflammation of the parotid glands in mumps. This history, however, proves that such a course of events may take place.

EXPERIMENTAL NOTE.

SOME EXPERIMENTS RELATING TO THE TOXIC NATURE OF THE URINE OF DIPHTHERIC PATIENTS.

BY CLARENCE O. AREY, C.E., M.D.,
OF CLEVELAND, OHIO;
PATHOLOGICAL LABORATORY, WESTERN RESERVE UNIVERSITY.

THE following experiments were made during the past winter with the object of determining what action the urine (and its products) of diphtheric patients would have upon animals, and inferring as far as possible from this the nature of these products. The experiments are far from complete, but they were continued throughout the winter and were carried as far as my resources would allow.

On October 26, 1894, I received, through the courtesy of Dr. C. C. True, a specimen of urine from Miss F., a school-teacher, who had contracted a disease, clinically diphtheria, from two of her pupils. A bacteriologic diagnosis failed to disclose the presence of Klebs-Loeffler bacilli, and before a second examination could be made the young lady died. As it was very difficult to obtain such urine as I wanted, I proceeded with this urine and made Experiments A, B, C, D, E, mentioned further on in this article.

This urine was examined with the following results:

Specific gravity, 1028; reaction, acid; color, between a *café olée* and a salmon, being very cloudy. There was an excess of uric acid. Albumin was present in large quantities. No sugar was found. The urine was sterile both by microscopic examination and by culture-methods.

After examination the urine was treated as follows: To one part was added 0.02 per cent. carbolic acid. This is designated No. I. Another portion was slowly sterilized; that is, it was subjected to a temperature of 60° C. for one hour each day for five consecutive days. This

treatment cleared up the color described, leaving a clear urine, with a slight white deposit at the bottom of the flask. Upon standing several days after sterilization the original color and cloudiness returned.

Thirty parts of this urine were added to sixty parts of agar-agar. The mixture was rendered amphoteric, and after hardening in a slant after sterilization, it was inoculated with a pure culture of diphtheria-bacilli. There was no growth in the tube.

This urine was kept for several weeks without opening, when carbolic acid was added to the extent of 0.5 per cent. The urine was then filtered and the filtrate designated I *a*. This filtrate yielded a precipitate when heated, when absolute alcohol was added, and when a saturated salt-solution was added.

A portion of the filtrate I *a* was precipitated by the addition of salt to saturation, the precipitate filtered out and the resulting filtrate designated I *b*. Another portion of the filtrate I *a* was precipitated by the addition of absolute alcohol and filtered, the filtrate being designated as I *c*.

Another portion of the filtrate I *a* was precipitated first with salt and filtered, and this filtrate precipitated with absolute alcohol and filtered. This last filtrate was designated as I *d*.

The following experiments were made upon animals. All inoculations with these products and the products of other urines were made subcutaneously with the hypodermic needle:

Experiment A. An old guinea-pig was given 1 c.cm. of the urine No. I that had carbolic acid added to it to the extent of 0.02 per cent. The weight of this pig was not taken at the time of inoculation. The animal died twelve days later, the post-morten examination showing the typical lesions of experimental diphtheria.

Experiment B. A guinea-pig weighing 330 grams was inoculated with 0.75 c.cm. of I *a*. Four days later this same pig was given 1 c.cm. of I *a*. The animal died thirteen days after the original inoculation. The typical lesions of experimental diphtheria were found after death.

Experiment C. A guinea-pig weighing 340 grams was inoculated with 1 c.cm. of I *b*. This animal died ten days later, and the autopsy showed the typical lesions of experimental diphtheria.

Experiment D. A guinea-pig weighing 305 grams was inoculated with 0.9 c.cm. of I *c*. This inoculation was repeated three days later, 1 c.cm. of the fluid being used. The animal died seventeen days after the original inoculation, having lost 80 grams in weight. The post-mortem examination showed that the animal died of pneumonia. Besides the lesions of the lungs, however, there was an excess of serous exudate in the peritoneal cavity, with slight hyperemia of the tissues.

Experiment E. A guinea-pig weighing 290 grams was inoculated with 1 c.cm. of I *d*. This injection was repeated two days later. The animal died seventeen days after the first inoculation, having lost 30 grams in weight. The post-mortem examination showed an intussusception of the bowels, with much inflammation surrounding it.

In the foregoing experiments two of the deaths were accidental; the remaining three showed lesions identical with those of experimental diphtheria. The question arose, Could not these lesions be produced by the toxic properties of the urine itself, from the urea and other elements contained? To answer this question the remaining experiments were conducted with products taken from the urine and held in aqueous suspension in the manner to be described; and as a check-experiment a guinea-pig weighing about 300 grams was inoculated with 1 c.cm. of the urine of a patient free from diphtheria. The inoculation had no perceptible effect upon the animal. In all of the following experiments the diphtheria-bacillus was found in the throats of the patients.

On December 22, 1894, Dr. William T. Howard, Jr., brought me a bottle of urine from a patient sick with diphtheria, who had previously been treated with the antitoxin. This is designated as urine No. II. Examination of this with the microscope showed no bacteria; cultures from it, however, showed the presence of microorganisms, but there were none of the Klebs-Loeffler variety. A piece of camphor about 1 c.cm. in diameter was added to about 100 c.cm. of this urine. Examination one week later with the microscope showed a multitude of organisms. Carbolic acid was then added to the extent of 0.5 per cent.

This urine was treated as follows: 94 c.cm. were taken and fitered; the residue was suspended in 11.5 c.cm. of distilled water, to which sufficient carbolic acid was added to make 0.5 per cent. This suspension was designated II *a*. All filtering was done through heavy filter-paper In this case the residue in suspension contained the bodies of many dead bacteria.

Experiment F. A guinea-pig weighing 170 grams was injected with 1 c.cm. of II *a*. Forty-six days later this animal weighed 240 grams, and was then again injected with 1 c.cm. of II *a*. This injection was followed by the minimum lethal dose of a freshly tested diphtheria-toxin. This toxin had had its minimum lethal dose determined five days previously. The animal was alive one month later, when the laboratory closed for the summer.

Experiment G. A guinea-pig weighing 360 grams was injected with 1 c.cm. of II *a*, followed on the opposite side of the body by the minimum lethal dose of diphtheria-toxin. This animal died four days later from anthrax contracted from an infected cage.

On December 31, 1894, Dr. Miller, of the Ohio State Board of Health, brought me a bottle of urine from a child, two years old, suffering from diphtheria. The urine was obtained on the sixth day of the disease. The specific gravity was 1022, the reaction acid. Albumin and uric acid were present. Petrie plates made from this urine showed four small colonies, none of them being diphtheric. The case had been treated with the antitoxin of diphtheria.

On January 9, 1895, Dr. Hopkins, the Health-Officer of Ashtabula, Ohio, brought me a bottle of urine from a young lady who had been suffering from diphtheria, but had been convalescent for five days when the urine was obtained. No antitoxin had been used in this case. The specific gravity was 1022, the reaction neutral. Albumin was present in large quantities, but there was no sugar. Cultures showed a few organisms, but no diphtheria-bacilli. This urine was treated as follows: One-half of the urine passed in twenty-four hours was filtered, and the residue was suspended in 37.5 c.cm. of distilled water, to which 0.5 per cent. of carbolic acid was added.

This residue was examined under the microscope, and contained mostly an amorphous sediment, with some mucin and some small epithelial cells. This is designated as IV *a*.

The filtrate was rendered alkaline with sodium hydroxid, which precipitated some of the phosphates. These phosphates were washed off the filter with distilled water to which 0.5 carbolic acid had been added. The filtrate from this last had sodium chlorid added to saturation, causing precipitation. This precipitate was suspended in water in the manner already detailed. To the filtrate from this last, one-third of its volume of absolute alcohol was added, causing a crystalline precipitate in twenty-four hours. The crystals were like the phosphates when examined with the microscope, except that the surfaces had a peculiar feathery appearance. The crystals were suspended in 50 c.cm. of water, when they became amorphous. A portion of the suspension was tested with ammonium molybdate, and yielded the reaction for phosphorus. This last suspension is designated IV *b*.

The filtrate from this last precipitation was tested for albumin, and yielded a heavy deposit.

Experiment H. A guinea-pig was inoculated with 1 c.cm. of IV *b*. The animal was not weighed until eight days after inoculation, when its weight was 375 grams. Thirteen days later than this its weight was 405 grams. At this time the injection of 1 c.cm. of IV *b* was repeated. The animal died fifty-four days after the original inoculation, weighing 310 grams at death. A post-mortem examination showed inflammation of the inguinal glands and of the suprarenal capsules. The heart was much dilated. There was no excess of fluid in the serous cavities.

Experiment I. A guinea-pig was inoculated with 1 c.cm. of IV *a*. Five days afterward it weighed 285 grams; fifty-three days later 310 grams. The animal was now injected with 1 c.cm. of IV *a*, followed by the minimum lethal dose of the diphtheria-toxin already mentioned. This experiment was made five days after the test of the toxin. Sixteen days after this last inoculation the animal weighed 325 grams.

Experiment J. A guinea-pig weighing 240 grams was injected with 1 c.cm. of IV *a*, followed on the opposite side of the body by the minimum lethal dose of the same toxin used in the other experiments. This experiment was made twenty-six days after the toxin was tested. The animal suffered no inconvenience from the injections.

Another bottle of urine was brought me from Ashtabula. This was treated in the same way as No. II, the residue from 40 c.cm. of urine being suspended in 17 c.cm. of distilled water, to which carbolic acid was added to the extent of 0.5 per cent. This suspension is designated V *a*.

Experiment K. A guinea-pig weighing 215 grams was inoculated with 1 c.cm. of V *a*. This animal died forty-one days later, weighing 235 grams. The autopsy showed inflammation of the inguinal glands. The injections in all experiments were made uniformly in the inguinal region. There was an excess of serum in the peritoneal cavity. The right suprarenal capsule was inflamed and perhaps the left one also. The other organs were normal.

The diphtheria-toxin used in all of these cases was the same. Its strength was determined on four different guinea-pigs before being used in these experiments. Some six weeks later this toxin was found to have lost its virulence, thus invalidating experiments that were not made with it immediately after its strength was tested.

SUMMARY. A noticeable point is that none of the urine examined was found to contain bacilli of diphtheria. The experiments from A to E, inclusive, showed toxemia. From the experiments from F to K, inclusive, the following deductions can be made:

Experiment F would tend to show either that the urinary product II *a* was a mild toxin and protected the animal against a fatal dose of diphtheria-toxin after sufficient time had elapsed for immunity to be acquired, or that this product was an antitoxin that protected against the fatal dose of diphtheria-toxin when given either before or at the same time as the diphtheria-toxin.

Experiment G was uncertain in its results.

Experiment H seems to show that the second dose of IV *b* was given before the animal had recovered from the effects of the first inoculation, and that the animal died of slow poisoning, IV *b* being a toxin.

Experiment I shows the same results as F, thus indicating that IV *a* was either a toxin or an antitoxin.

Experiment J would show, if the diphtheria-toxin had remained virulent, that IV *a* was an antitoxin, IV *a* being inoculated at the same time as a fatal dose of diphtheria-toxin.

Experiment K would show slow poisoning, with a gain in weight. As the stock of toxin in the laboratory had failed, leaving some of the experiments in doubt, I sent some of the suspension IV *a* to Dr. J. H. Wright, of the Sears Laboratory of the Harvard Medical School, to see if he found any antitoxic properties in it. The following is his report:

"The material in the small bottle (IV *a*) has been tested with negative results, no antitoxic power being shown. The test was as follows:

"Guinea-pig No. I, weight 640 grams, received subcutaneously 1 c.cm. of your fluid, and immediately afterward $\frac{4}{10}$ c.cm. of diphtheria-toxin, also subcutaneously. Death followed about the fifth day, with the characteristic lesions of toxin-poisoning, identical with those of experimental diphtheria.

"Guinea-pig No. II, whose weight was 640 grams, received subcutaneously 1 c.cm. of your fluid, and immediately afterward $\frac{4}{10}$ c.cm. of toxin, also subcutaneously. Death followed in about four days, with the characteristic lesions of toxin-poisoning, as in the case of pig No. I.

"The toxin used was tested a few days before on a pig of 520 grams' weight, death following in about four days with the characteristic lesions. It is apparent, therefore, that the material submitted by you has no neutralizing effect upon the toxin of diphtheria."

These experiments of Dr. Wright's, coupled with my own, would tend to show that all the products used were toxins; those in suspension being of a milder character than those used in the Experiments A, B, C, D, and E, which contained all the elements of the urine except the residue precipitated out in each case; the albumins contained in the urine in these first five experiments being probably the most toxic agents. The products used after Experiment E contained practically no

albumin, and were not uniformly fatal, as were the experiments preceding E. In the experiment in which non-diphtheric urine was used no evil effects were produced, showing that the constituents contained in one c.cm. of such urine were not toxic.

A review of these experiments brings the following questions to mind: To what extent would it be possible to use these milder toxic products of the urine in cases of contagious disease in conferring immunity to such diseases? If possible, how could the necessary dose be ascertained? Cannot such a method be applied to diseases in which the exciting cause is not now known? Thus, in a disease like pertussis, in which the toxemia is not marked, might not an increase of the toxin stimulate the body-cells to greater reaction and a consequent more rapid development of the neutralizing material that produces the ultimate immunity to the disease?

Could a child that had been exposed to scarlet fever be protected by the injection of a mild urine-toxin whose toxic strength had been ascertained?

In conclusion, I have to thank Dr. William T. Howard, Jr., for many suggestions during the course of the work, and for the help of his assistants when necessary.

MEDICAL PROGRESS.

Cycling and Heart-disease.—As the result of a considerable observation extending over a period of eighteen years, BENJAMIN WARD RICHARDSON (*Asclepiad*, vol. xi, No. 43, p. 225) thus summarizes his conclusions as to the influence of cycling on the heart: Cycling, when carried on with moderation, may, in so far as the healthy heart is concerned, be permitted or even recommended. It is not necessary to exclude cycling in every case of heart-disease. It may even be useful in certain instances in which the action of the heart is feeble, and in which signs of fatty degeneration are found; as increased muscular exercise often improves the condition of muscle, and of no muscle more than the heart itself. As the action of cycling tells directly upon the motion of the heart, the effect it produces upon this organ is phenomenally and unexpectedly great in regard to the work it gets out of it. The ultimate effect of severe cycling is to increase the size of the heart and to render it irritable and hypersensitive to motion, the cycling acting upon it like a stimulant. The overdevelopment of the heart under the continual overaction, and extreme overaction, affects, in turn, the arterial resilience, modifies the natural blood-pressure, and favors degenerative structural change in the organs of the body generally. In persons of timid and nervous natures, "neurotics," the fear incidental to cycling, especially in crowded thoroughfares, is often creative of palpitation and disturbance of the heart, and ought to be taken into account in preventive advice. In advising patients on the subject of cycling it is often more important to consider the peripheral than the central condition of the circulation. Enfeebled or worn-out arteries, that is to say, are more endangered than the feeble heart, and, when connected with a heart that is overactive, are seats of danger. This same remark would, of course, apply to cases in which there is local or arterial injury, as in aneurism. Venous enlargement seems rather to be benefited than injured by cycling, and conditions marked by sluggish circulation through veins are often greatly relieved by the exercise. There are three sets of acts that are most injurious in cycling: (*a*) Straining to climb hills and meet headwinds. (*b*) Excessive fatigue. (*c*) The process of exciting the heart and wearing it out sooner by alcoholic stimulants, to the omission of light, frequently repeated, and judiciously selected foods.

The Maternal and the Fetal Blood at Birth.—As the result of a series of clinical observations, ELDER and HUTCHISON (*Edinburgh Medical Journal*, August, 1895, p. 105) have found that the blood in the newly born child is relatively richer in red corpuscles than that of the adult by from 350,000 to 500,000 per c.cm. For a short time after the birth (up to about two days) the red corpuscles seem to increase in number. This is probably due to the fact that the total volume of blood is less, from the fluid lost from the body during this time being in excess of that absorbed. Thus concentration of the blood is produced. After the second day or so the red corpuscles gradually decrease. The number of red corpuscles varies much more than in adults, probably because of greater variations in the total volume of the blood. At birth there are always present a considerable number of nucleated red corpuscles. They vary, however, in number in different cases. About the sixth month of intrauterine life the number of nucleated red cells is very much greater than at birth. They probably decrease in number during the later months of pregnancy, and altogether disappear from the blood a few days after birth. The blood of the newly born child is relatively much richer in hemoglobin than that of the adult. The mother at parturition is anemic. In any individual case the blood of the mother is considerably poorer in red corpuscles per c.mm. than that of her child, and it is still more deficient in hemoglobin. Both the blood of the mother and that of the child contain a larger number of white corpuscles than normal adult blood. The blood of the mother may be quite as rich in white corpuscles as that of the child. The blood of the child contains a distinctly larger proportion of lymphocytes and a distinctly smaller proportion of neutrophile leukocytes than the blood of the adult; the number of eosinophile cells seems to be slightly deficient. At the sixth month this excess of lymphocytes is probably even more marked than at birth; these probably decrease during the latter months of pregnancy. After parturition the number of white corpuscles in the blood of the mother (at least when she suckles her child) decreases markedly in a few days.

Alcoholic Disease of the Heart.—FISHER (*Bristol Medico-Chirurgical Journal*, vol. xiii, No. 48, p. 81) devotes an interesting communication to the discussion of alcoholic disease of the heart. He points out the relative frequency with which cardiac hypertrophy is found at post-mortem examination in the absence of the ordinary causes of that condition, such as valvular disease, arterial sclerosis, and granular kidney. In many of these cases investigation will disclose a history of alcoholism. Clinically, cases of this kind are likely to present shortness of breath on exercise and cyanosis, with palpitation of the heart and precordial pain. The face is often congested, and edema develops in time. The cardiac impulse is diffuse, feeble,

and ill-defined. The area of cardiac percussion-dulness is increased, or it may be obscured by emphysema of the lungs. Auscultatory variations may also be present, such as duplication of one or other sound, and valvular murmurs may be audible. The disorder may result in sudden death. The treatment of alcoholic disease of the heart differs little from that of other forms of cardiac insufficiency, and includes rest in bed, with a withdrawal of the causative stimulant. Exceptionally, however, in an emergency, alcohol will have to be used. Some authorities, on the other hand, maintain that rest in bed should, if possible, be avoided, as it is believed that the circulation is thereby hampered rather than aided, as muscular action and comparative deep respiratory movements no longer aid in propelling the blood onward. From this point of view, also, digitalis is considered harmful, and strychnin nitrate valuable, with the addition of musk, castoreum, and valerian. In these cases also systematic bathing and exercise are considered useful.

—

Retraction of the Lower Chest Posteriorly as a Sign of Chronic Pericarditis.—BROADBENT (*Lancet*, No. 3752, p. 200) calls attention to a hitherto unpublished physical sign in the diagnosis of chronic pericarditis. This consists in a visible retraction, synchronous with the cardiac systole, of the left back, in the region of the eleventh and twelfth ribs, with sometimes, also, similar retraction of less degree upon the right side. Four cases are reported, all of which presented a definite history of pericarditis, and three, also, other conditions suggesting an adherent pericardium. It is explained that the only means of causing the retraction referred to upon both sides seemed to be the diaphragm, which if pulled upon would have more effect upon the floating eleventh and twelfth ribs than on the other more fixed ones. In cases of large heart with adherent pericardium there is a considerable area of the ventricles closely adherent to the central tendon of the diaphragm, and the powerful contraction of the hypertrophied heart must give a decided tug to this structure. That it should affect the ribs more often on the left side would be expected, from the adhesion being mainly to the left of the middle line. The liver also, which is often large in these cases, may restrain the movement on the right.

—

Thrombosis and Rupture of the Heart in an Infant.—EDRIDGE-GREEN (*British Medical Journal*, No. 1796, p. 1202) has reported the case of a boy, nine-and-a-half months old, who died without apparent cause. He was one of twins, and had been delicate and subject to convulsions from birth. On the day of his death he was seated on his grandmother's lap, when he was seized with a fit and died in three minutes. The fit was said to be different from those that had preceded it, and the child had appeared quite well previously. On post-mortem examination the pericardium was found distended with fluid blood, and the right ventricle presented a rupture one-third of an inch in length. This was gaping and started at about the middle of the ventricle, at its junction with the ventricular septum. On opening the right ventricle a loose, white thrombus was found in the cavity. It was one inch long, one-third of an inch wide, and one-quarter of an inch thick. Between the columnæ carneæ of the right ventricle were situated two small thrombi. The walls of the right ventricle were stretched, but appeared normal in other respects. The remainder of the heart and the other organs were normal.

—

Facial Paralysis with Unilateral Lacrymation.—FRANCKE (*Deutsche medicinische Wochenschrift*, 1895, No. 33, p. 532) has reported a case that lends support to the belief that a part of the nervous supply of the lacrymal gland is received through the facial nerve. The patient, a woman, was seized with vertigo that became so pronounced as to compel her to go to bed. At the same time a rumbling and roaring in the head developed, together with left-sided headache. Further, a considerable degree of impairment of hearing was present at first. Some eight days later complete paralysis of the muscles in the distribution of the left facial nerve developed and hearing was entirely lost. No derangement of function in the distribution of the fifth nerve could be discovered. The left eye was suffused with tears from defective action of the eyelids. Emotion induced lacrymation upon the right side, but not upon the left. The sense of smell was impaired so that reflex lacrymation could not be induced.

—

Paulocardia is the designation given by RIESMAN (*Philadelphia Polyclinic*, vol. iv, No. 36, p. 363) to the subjective sensation of intermission or stopping of the heart sometimes observed in cases of gastric neusasthenia. In some instances this phenomenon is obviously due to pressure of the distended stomach against the heart through the diaphragm. In other instances it is probably reflex, the afferent pathway being through the gastric branches of the vagus. Further, toxic agents circulating in the blood can by direct action on the proper centers or nerves give rise to the condition.

SATURDAY, SEPTEMBER 21, 1895.

THE REPORT OF THE PHILADELPHIA BUREAU OF HEALTH FOR 1894.

THE annual report of the Bureau of Health of the city of Philadelphia for the year 1894 has just appeared, and, like the previous reports of this important bureau, is a volume of considerable size. Of the 700 printed pages, however, nearly 300 could be dispensed with, as they contain a detailed record of interments for each month in the year, which could readily be embodied in a summary of four or five pages.

The report of the President of the Board, Dr. William H. Ford, states that while no epidemic occurred during the year there were more cases of smallpox than in any year since 1888—126 cases, with 13 deaths. Diphtheria maintained its virulence, the deathrate being considerably higher during the last three years than for any years previously. Scarlet fever, typhoid fever, and pulmonary tuberculosis show a lower deathrate from year to year. The deathrate of the city, excluding the stillborn, was 19.90 per 1000. The deathrate of children under five years of age was 7.4 per 1000 of the whole population, forming 37 per cent. of all the deaths.

The birthrate, exclusive of the stillborn, was 25.63 per 1000. The number of births registered still falls considerably below the actual number born. In 1890 it was estimated that at least 10,000 births were not recorded. Chicago reported in 1894 a birthrate of 38.7 per 1000, or 60,600 births in a population of 1,567,727. Philadelphia has 31,226 registered births in a population of 1,139,457. If the birthrate we reequal to that of Chicago, 13,000 births would remain unregistered. Of the births, 2.15 per cent. are recorded as illegitimate, but no accurate returns on this subject are attempted.

The new features introduced during the year were the insistence on either private or official disinfection of apartments in which deaths from pulmonary tuberculosis had occurred (the medical inspectors visiting all such premises); the establishment of a bacteriologic laboratory; the incineration of garbage; the collection of garbage in covered iron carts, so as to conceal odor and prevent dripping of the fluid contents; and the use of the tuberculin-test in the examination of all herds furnishing milk to the city. The amount of money expended by the Board for the year was $213,674.

In the reports of the various divisions many interesting features are presented. It is unfortunate, however, that the numerous tables contained in the report are not computed on the basis of the population. The mere statement that a certain disease caused a greater number of deaths in one year than in another does not indicate that there has been an actual increase in the rate per thousand, the increase in population often being sufficient to account for the greater number of deaths. The mortality of children under five years of age ought to be computed on the number living in that age-group.

There seems to be no decrease in child-mortality; dividing the table on page 151 of the report into four quinquennial periods, we see that the mortality of children under five years was annually from 1875 to 1879, 7.7 per 1000 of the whole population; from 1880 to 1884, 8.0 per 1000; from 1885 to 1889, 7.8 per 1000; from 1890 to 1894, 7.7 per 1000.

Pulmonary tuberculosis is returning a smaller number of deaths from year to year. According to our own computation from the figures furnished in the report, the average number of deaths annually from this cause in the period from 1880 to 1884 was 32 per 10,000 of the population; from 1885 to 1889 was 28 per 10,000; from 1890 to 1894 was 25 per 10,000.

The deaths from pneumonia and heart-disease are

increasing in frequency, and tend to balance the decrease in such diseases as typhoid fever and tuberculosis; nor can the increased number of deaths from pneumonia be ascribed to a greater number of individuals of advanced age living who escaped death from other causes and finally succumbed to inflammation of the lungs. The number of persons dying of pneumonia between the ages of sixty and eighty years has not increased perceptibly in the last few years.

The report of Dr. Welch, of the Municipal Hospital, shows that 465 cases of diphtheria were admitted during the year, of which number 154 died (33.12 per cent.). There were 129 cases of scarlatina, with a mortality of 8.53 per cent.; and 87 cases of variola and varioloid, with a mortality of 11.49 per cent.

"All the children under five years old admitted with smallpox were unvaccinated," and the percentage of death among them was 28. Of 21 cases vaccinated in infancy, with good marks remaining, none died; of 13 cases vaccinated and showing poor scars, 2 died. Thus of the 34 vaccinated, 2 died, or 5.88 per cent.; of 44 unvaccinated, 8 died, or 18.13 per cent. Nine cases vaccinated after exposure recovered.

Dr. Taylor, in his report on sanitary inspection of the schools, makes some very pertinent remarks concerning the lack of supervision by the teachers over the health of the pupils, and recommends that principals be instructed to send all children presenting the slightest appearance of sickness to be medically examined, in order to arrest contagious diseases in their incipiency. He finds that "the schools are large factors in the spread of contagious diseases." Most of the schools are improperly ventilated; and garments are thrown into dark closets or hung around the schoolroom.

The certificates of medical men, other than the duly appointed medical inspectors, stating that the prescribed period after a contagious sickness has passed, can, according to the new ruling of the Board of Health, no longer be accepted. This period is thirty days in all cases.

The Inspector of Milk has much to complain of. First, the influence of selfish milkdealers has operated to prevent proper legislation on the subject; and second, in instances in which legislation exists, Magistrates are liable to be influenced by the political friends of the accused. If a milkman does not know that his milk is adulterated, he is not liable to the penalty. The Inspector wisely contends that "the milkman should be *required* to know that his supply of milk is free from added water, and that it contains its normal percentage of cream." About 300,000 quarts of milk are used every day in Philadelphia, and with the present number of inspectors it is possible to examine only about 1000 quarts a day, so that no efficient control can be said to exist. We understand that the inspectors only undertake investigations when suspicion has been directed against a dealer. Much difficulty is also experienced in enforcing cleanliness in city dairies, where distillery-swill and vegetable refuse are likely to be used as food.

The Inspector of Nuisances advises the more general use of public garbage-boxes constructed of steel. Such boxes should be plentifully supplied, especially in the more densely populated districts, and the people should be taught to use them, instead of using the street as a receptacle for garbage and waste paper. A few arrests on any street on which this nuisance exists would soon teach the residents a lesson in cleanliness that they seem to refuse to learn in any other way.

The small streets are being rapidly provided with better pavements, but unfortunately many of the newer alleys in the upper portion of the city are paved with Belgian block instead of with asphaltum. Brick or Belgian block paving allows the drainage to soak into the ground and weeds and slime to form upon the surface. Much is yet needed in improved pavements, and the underdrainage of all premises ought to be proceeded with as rapidly as possible; the only entrance to many court-properties is through a narrow alley, where the surface-drainage obliges one to wade through the refuse water.

Privy-wells and cesspools to the number of 2226 were abandoned during the year; but the number in use in the thickly settled districts is still great, and no abatement in the removal of these nuisances should be tolerated.

On page 64 of the report, the Coroner furnishes a table of inquests, from which it appears that 140 suicides and 31 homicides occurred during the year. The street passenger-railways disposed of 67 persons, the trolleys being responsible for 43 deaths of this number. The steam-roads killed 169 individuals. Eighty-four deaths occurred from drowning.

The Health-bureau of the city of Philadelphia is a branch of the Department of Public Safety.

It consists of the Board of Health, composed of five members (who serve without remuneration), a health-officer and the port-physician. Its various divisions are that of Vital Statistics, managed by a chief clerk, nine assistants, and two collectors; that of Contagious Diseases, superintended by a chief medical inspector and fifteen assistants, all doctors of medicine; the Nuisance Division, with a chief and twenty-two assistants; the Division of House-drainage, with a chief and twelve assistants; that of Milk-inspection, with a chief and nine assistants; the Division of Bacteriology, with a chief and two assistants and a chemist. The Municipal Hospital and twenty-three vaccine physicians are also under the control of this department.

The Philadelphia Hospital and the district charity physicians, however, are under the supervision of the Department of Charities and Correction and have no connection with the Health-department. The Coroner's office is likewise separate and distinct. We see no good reason why the Health-bureau should not include also the City Hospital and all that pertains thereto. The Almshouse could readily be divorced from the hospital and placed under separate management, and the separation would be advantageous in more ways than one.

While the Coroner in his official capacity deals largely with legal matters, the office is in reality a medicolegal one, and it would be an advantage if it were filled by one possessing both the qualities of a jurist and those of a physician. Agitation looking to reform in this direction has for some time been going on in New York. Massachusetts in 1877 abolished the office of Coroner and has a medical examiner instead, the legal work being in the hands of the judges of the courts.

Upon the Department of Health of a large city devolve many and varied duties. The service has grown gradually to huge proportions, and the power lodged in the hands of the department is almost absolute. Buildings must be constructed in conformity with its sanitary rules; certain lines of trade must be carried on according to its directions; houses must be maintained in a specified condition, and must be repaired in accordance with its instructions; when sickness occurs the department's directions must be complied with; burials must take place in accordance with its rules; births and marriages must be recorded on its books; food for consumption must bear the stamp of its approval; even private property is under control of the health-authorities, and can be destroyed at their will. We do not in any way wish to contend that these things are not all proper. If the health of a community is to be protected and disease is to be prevented, the power to enforce necessary regulations must be properly centralized, at least until all individuals will voluntarily obey the laws. But how far is this power to extend, and who shall exercise it? If prevention of disease is the province of a board of health, shall such a board stop short of anything to attain its purpose? Instead of a merely regulating body, a sanitary police as it were, shall it not itself undertake to produce the conditions that are necessary to the maintenance of health?

To illustrate, shall it simply order the destruction of unsanitary hovels, but shall it not also secure the construction of model dwellings for the poor, as the municipality of Glasgow has done and the municipality of London contemplates doing? Shall it have its own model dairies for supplying suitable milk for children at a nominal price? Shall it operate summer sanitariums and "country-week" farms, or at least control them? Such a policy has been urged in European cities, and is not out of harmony with American institutions. The duties that some of our health-boards now assume are of a similar nature, such as bacteriologic and chemic examinations; disinfection of dwellings and personal apparel, the management of hospitals, and the manufacture of antitoxins and vaccines.

Those who see in such an extension of power an unwarranted infringement upon private rights and privileges are loudly opposed to it. On the other hand, those who are desirous of governmental control of all the means of production and distribution welcome each step in this direction.

If a State is founded for the purpose of promoting the general welfare of its citizens and their posterity, any measure that has for its purpose the prevention of disease has a reason for existence and execution.

When the great mass of people learn to recognize the need for the execution of health-laws they will practise them without compulsion, and laws will not be considered restrictive. They will feel it as much a duty to quarantine the sick of their families until the danger is past as they now consider it a duty to educate their children. Who knows but perhaps expectoration on the public highways will some day be regarded as much an offence as urinating in public is now.

If health-rules are carefully considered before

they become operative, if the public is taken into confidence and educated to understand the aims and purposes of laws, and if physicians will consider themselves as the expounders and teachers of, and will advise obedience to, such health-ordinances, not only will the work of the Health-department be made easier, but the healthfulness of cities will also be greatly increased.

CONTINENCE AND HEALTH.

THE Medical Faculty of the University of Christiana, in Norway, is reported to have replied to an inquiry addressed to it in relation to continence, that "The recent declaration made by different persons that a chaste life and continence are injurious to health is, according to our view, wholly false. We know of no disease or of any weakness which can be said to be the result of a perfectly pure, chaste life."

We are perfectly aware that there are some physicians who, whatever their private doubt may be about the unwholesomeness of continence, do not hesitate to recommend to some of their patients immoral sexual indulgence. We have always suspected that they do this not because they believe in the injurious effects of continence, but rather in a spirit of compromise with vice, and from a selfish motive to preserve their prestige with a class of patients to whom immorality is more desirable than a strict, personal hygiene. It is a specious argument, which is met without opposition, that sexual gratification is a physiologic necessity. It is a prescription that popularizes the physician because it gratifies the patient. It is a dose that requires no sugar-coating for some, because the moral gustatory sense of the patient is blunted to that degree that he does not perceive the sophism that distinguishes between a law of Nature and a law of ethics.

We do not stop here to point out in detail that the laws of ethics are only the higher laws of Nature—not opposing the latter, but confirming and regulating them. "Nature" is only the universal group of phenomena, of which man's moral sense is the highest, the most complex, and the most highly differentiated phenomenon. From even the purely biologic standpoint it is easy, nay necessary, to affirm that ethics is the physiologic activity of the highest evolved product in organic nature—the human conscience. We leave this aspect of the subject, in order to discuss briefly its practical bearings, which at least appeal to the intelligence of those who persist in regarding this grave question from a lower plane.

In the first place, we may affirm emphatically that sexual immorality is the prime and persistent cause of the prevalence of venereal diseases. This statement is not weakened by the fact that venereal diseases may be acquired and transmitted innocently. This very fact, appalling in itself, is only an additional argument against the vice that primarily breeds and disseminates them. We believe that any general prophylaxis against gonorrhea and syphilis will always be counteracted by the prevalence of prostitution. If we could imagine prostitution abolished, we could imagine the prompt eradication of these scourges. Without its abolition we cannot. Those who believe that its legal control (in itself a sociologic chimera) can prevent the dissemination of infection occupy an unscientific ground, which is not assumed in reference to any other infectious disease. The first necessity of prophylaxis against pathogenic organisms is to abolish the conditions under which they thrive. The favorable conditions for gonorrhea and syphilis are prostitution. Does any rational man believe that the mucous surfaces of the urethræ and vaginæ of libertines and courtesans can be so sterilized and kept sterile as to eradicate the gonococcus? When we combat diphtheria, do we send our children to consort with patients in whom there is the slightest suspicion of an infected pharynx? Moreover, is it the function of a member of the medical profession to sterilize vaginæ (with indifferent prospects of success) in order that they may be exposed to prompt reinfection? Is this according to the best bacteriologic methods of the day?

We dwell in no Utopia. We do not expect to see prostitution abolished, and therefore we expect to have to combat the ravages of secret diseases all our professional days. Therefore we desire that no other man should dwell in any Utopia of his own making, because his Utopia, we are convinced, is only a Tartarus. From our point of view the physician who recommends sexual immorality is untrue not only to the ethics but to the science of medicine. He aids by his advice in the dissemination of the germs of disease. He is blind to the teachings of bacteriology; he is indifferent to the claims of a profession whose highest aim and endeavor are the prevention and eradication of disease.

Secondly, from this standpoint it would make no difference even though continence were somewhat

of a trial to health—of which there is but little scientific evidence. But even if it were, the obscure neurotic and emotional disturbances that are laid at the door of continence are as nothing compared with the effects of the venereal diseases.

But is there any evidence that continence is injurious to health? In discussing this question in a dispassionate and purely scientific spirit we do not care to say dogmatically that there is none. We can safely admit that there is perhaps evidence that some strictly functional disturbances, confined largely to the psychic sphere, do occasionally manifest themselves, in persons of a certain temperament, as a result of a conscientious adherence to continence. It may even be admitted that hysteria must claim as among its causes emotional perturbations in which obscurely continence may act as a factor. But this admission in nowise changes either the ethical or the scientific considerations involved. In much graver crises the law of duty often demands the imperilling or even the sacrifice of a much larger measure of health. Dare the medical profession, which applauds the self-sacrifice of life in attendance upon pestilence, stultify itself by admitting that a man or a woman is not bound to observe the law of sexual morality lest he or she should suffer the trifling or periodic disturbances of the nervous system that wait upon continence? Are these so grave that they cannot be withstood? Is there no cure or control for them? Have not men and women withstood them successfully for years, while libertines and their posterity have decayed away under the ravages of syphilis? If physicians are to advise their patients by no higher law than the law of probabilities and expectancy of life, which of these two alternatives are they bound to offer to them?

As we said in the beginning, we discuss this question not upon the higher, but upon the lower, plane. We desire to make it clear as a purely scientific question. No physician can afford to pander to vice if for no better reason than because when he does so he ceases to be a scientist. And in one sense this is a high plane of thought, because it elevates medicine to its true position, as the beneficent source not only of healing, but of ethics.

A German physician has recently insulted his profession by recommending that sexual perverts should be hypnotized and then led by a series of obscene suggestions to indulge in normal but immoral intercourse. As the ancient Spartans made their slaves drunk in order to disgust their children, so it would seem has this German writer debauched his own patients in order to repel all decent men.

EDITORIAL COMMENTS.

The Longevity of Medical Men.—Of 140 obituary notices of physicians appearing in medical journals in the six months ending July 1, 1895, in which the age of the decedents is given, we find that death occurred between the ages of

25	and	30	. . . .	in	3	instances.
30	"	40	. . . .	"	4	"
40	"	50	. . . .	"	17	"
50	"	60	. . . .	"	19	"
60	"	70	. . . .	"	24	"
70	"	80	. . . .	"	39	"
80	"	90	. . . .	"	29	"
90	"	100	. . . .	"	5	"

Although this table can have no great scientific interest, as the period of time covered by the analysis is too short and the number of deaths too small to base any conclusions on, yet it seems remarkable that more than half the number should have reached the age of seventy and over. The notices were taken without selection as they appeared each week in the more important journals and are cosmopolitan in their nature.

Dr. Kortright, in an article in the *Brooklyn Medical Journal*, already referred to in these columns, gives 54.6 years as the average age at death of 450 medical men dying in New York City. In the New England States of all deaths of persons over thirty years of age only 38 per cent. occur after the seventieth year.

Of course, we realize that the foregoing list is likely to include only those who have attained some prominence in their profession, the immortal ones as it were, and fame comes chiefly to those who have had the strength to live, whereas the many who die young in the struggle are not recorded.

The nonogenarians included Lombardy, of Switzerland, who reached the age of ninety-two; Schmid, of Germany, aged ninety-five; Dufoy, of France, aged ninety-six; Ball, of England, ninety-six; and Calmeil, of France, ninety-seven. Among the octogenarians we have such names as Detmold, Baumgarten, Symes, Reich, Noeggerath, Danneberg, Ludwig, Guerin, and Parke; among septuagenarians, Goodsir, Vogt, Mundie, Vulpius, Thiersch, Verneuil, Symonds, and Lemaestre; and among sexuagenarians, Loomis, Gottstein, Dujardin-Beaumetz, Hulke, Tuke, Guillard, and Rosati.

Whether or not medical men have a shorter lease of life than other men is, after all, not of the greatest importance. "He liveth long who liveth well" is an old saying, and medical men aim to be useful, even in old age, if they are so fortunate as to attain it.

A New Woman's Medical College.—The first annual sessions of the Woman's Medical College of Kansas City, Missouri, will open October 15th. In the preamble of its announcement it is stated that after its first year the college intends to unite itself with the Medical College Association and have a four-year course. Why a beginning is made with a three-year course the trustees do not say, although in the same preamble the "insignia"

of the college is stated to be "quality rather than quantity." Another quotation is the following: "The time when medical colleges consider only their large number of matriculants as their success is past."

No student will be admitted under eighteen years of age, and the candidate for graduation must be, at least, twenty-two years of age, except students of 1895–96. Attendance on lectures and clinics will be compulsory, no one being admitted to examination unless 80 per cent. of the lectures have been attended.

The school hopes to draw its students from the South and Southwest. The faculty includes both men and women.

The Pennsylvania State Medical Examinations.—Our attention has been called to the fact that while the examinations before the Pennsylvania State Board of Medical Examiners were held on June 18th, the licence conveying the privilege to practise medicine in the State did not reach some of the successful applicants until August 28th, thus necessitating a considerable period of uncertainty and enforced idleness. It also appears that a neat income must accrue to the examiners, for upon the basis of 240 applicants at the last examination before the board representing the Medical Society of the State of Pennsylvania, each applicant paying $25, $6000 must have been paid in fees, while but an insignificant amount would have covered the entire expense. In view of these facts, it would appear more equitable to reduce the amount of the fee, as this must come from those ill able to afford it.

SOCIETY PROCEEDINGS.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Twenty-first Annual Meeting, Held in Detroit, September 3, 4, 5, and 6, 1895.

THE Association was called to order by DR. H. O. WALKER, of Detroit, Chairman of the Committee of Arrangements.

Prayer was offered by the REV. MARCUS A. BROWNSON, of Detroit.

DR. WALKER then introduced MAYOR PINGREE, who paid an eloquent tribute to the medical profession, and extended a cordial greeting to the Association.

THE ADDRESS OF WELCOME,

on behalf of Detroit physicians, was made by DR. J. HENRY CARSTENS, of Detroit.

Dr. Walker presented the President of the Association, DR. WILLIAM N. WISHARD, of Indianapolis, who delivered the

PRESIDENTIAL ADDRESS.

He pointed out the importance and advancement of Detroit as represented by the standing and intelligence of the local physicians. He referred to the beginning of the four-years' course in medical colleges, and said the fear that the new rule would operate to the disadvantage of the smaller schools was unfounded. He urged the advisability of publishing the records, papers, and discussions in some manner to make them accessible to all members. He recommended a permanent Executive Committee, and regretted that the large number of papers necessitated the holding of two meetings at the same time. He commended the preparations for the meeting, and pledged his earnest efforts to the promotion of the profit and pleasure of the convention.

The reports of the Secretary and Treasurer were read and accepted.

The reading of papers was proceeded with, the first one being read by DR. THOMAS HUNT STUCKY, of Louisville, entitled

THE GOLD-COMBINATIONS AS ALTERATIVES.

He related that at a meeting of the Medico-Chirurgical Society of Louisville, on April 5, 1894, he had exhibited a series of cases in which preparations of gold and arsenic were employed. He was under the impression at that time that the good effect claimed was produced in three ways: (1) By stimulation of the secreting glands of the stomach; (2) by the probable alterative effect upon these secretions; and (3) that probably there was a local antiseptic influence exerted. The class of patients in which the preparations had been employed included persons afflicted mostly with pulmonary tuberculosis, nephritis in its various stages, and chronic hepatic troubles, and convalescents. It was made a rule with all these cases to withdraw all medicine except the combinations of gold and arsenic. Four or five cases thus treated were detailed. One was in a man, sixty years of age, with tuberculosis. Eight drops of "mercuric bromid of gold and arsenic" were given hypodermically every four hours for a period of two months. No deleterious results were noticed. On the contrary, the patient was decidedly better, and his physical condition, color, appetite, and bodily strength improved.

A few cases were reported out of a large number to demonstrate that the combinations of gold and arsenic act as neither of the minerals does when administered separately.

The chemic differences were pointed out between auric and sodic chlorid and auric and arsenic bromid, with reference to their therapeutic action and subsequent elimination. It was contended that the combinations spoken of enter into the circulation as gold and arsenic and expend their force and exert their influence in an alterative way upon the glandular system; that a marked alterative effect is exerted upon all scleroses (non-malignant); that they act not only as a blood-maker but as a blood-builder, increasing not only the quantity but also the quality of the corpuscles; that under their use the hemoglobin is markedly increased; that they are eliminated by the kidneys; that they produce no irritation when given either by the mouth or hypodermically.

DR. WILLIAM F. BARCLAY, of Pittsburg, read a paper entitled

LEGITIMATE PHARMACY,

which he defined as that which meets the necessities and demands of the regular medical profession and the people. The medical profession is entirely separate and distinct from pharmacy. Medicines may be divided into four classes—patented, proprietary, non-proprietary, and secret. It was maintained that there are a large number of cures, mixtures, and tonics bearing the name of their originators and deserving of consideration as proprietary preparations. Pharmacists and physicians are interdependent, but should work together. Legitimate pharmacy has called into service educated and able men, but the incompetent and dishonest have got in too,

and cannot be too severely condemned. Pharmacists make errors, but physicians are careless, too, in writing prescriptions. Physicians should not favor particular pharmacists, and should not receive commissions from them. On the other hand, it is unworthy and unprofessional for pharmacists to prescribe drugs or medicines. Legitimate pharmacy should protect the people from the nostrum-makers. Physicians have a right to demand the highest skill and competence upon the part of the pharmacist, both for his own interests and for the good of his patients.

DR. F. E. STEWART, of Detroit, read a paper on

COD-LIVER OIL.

He pointed out the powerful stimulant action of cod-liver oil on nutrition, also demonstrating with specimens the differences in the color of oil digested from fresh livers and that prepared from putrid livers, the former being pale, golden or light-brown, according to the number of hours digested, and the latter dark-brown. The darker oils contain more extractive matter. It was held that the text-books contain many errors regarding the preparation of cod-liver oil.

DR. I. N. LOVE expressed himself as rather skeptical as to the value of cod-liver oil. He took the ground that there was danger of medical men becoming too professional, and said that that which brings relief to the patient is to be commended. He favored proprietary remedies that have come to the profession through pharmaceutic channels.

DR. D. TOD GILLIAM, of Columbus, read a paper entitled

UTERINE FIBROIDS—WHEN TO OPERATE.

He stated that the medical and electric treatment of uterine fibroids is to-day in a very unsettled state. While it cannot be denied that amelioration or even recovery has followed such lines of treatment, there has not been such a degree of uniformity in results as to inspire confidence. It was held that there is no better field for a competent observer than the study of the natural history of uterine fibroids. It will enable him to determine the true value of so-called curative agencies; will insure a more certain prognosis, and will give the proper cue to surgical interference. If out of 100 cases 90 suffering women can be restored to lives of usefulness and happiness, would it not be better to give them a chance? No surgeon is justified in performing hysterectomy or the more serious operations for uterine fibroids when the patient has not experienced sufficient trouble to make the condition a menace to her life.

DR. L. H. DUNNING, of Indianapolis, read a paper entitled

TUBERCULOUS PERITONITIS.

He considered the mode of invasion, the forms of the disease, the diagnosis and the treatment, and finally detailed a brief history of five cases. He said that tuberculous peritonitis with effusion is now universally considered a surgical disease. Even in the acute suppurative cases abdominal section yields a sufficient number of successes to render its employment imperative. Senn excludes all forms of the disease from surgical treatment except the exudative form. Manclaire names as the chief contraindications to surgical treatment the generalization of the lesion and the existence of profound systemic infection. Linder analyzes the results in 205 operations, with a mortality of 7.5 per cent. The deaths resulting in most of these cases were from collapse. When the tubes and ovaries are involved they should be extirpated. Dunning's experience in two cases leads him to the belief that the use of silk ligatures in tying the pedicle should, if possible, be avoided when it is necessary to remove the uterine appendages. A case was reported in a woman, aged fifty-six years, who came under observation for the extirpation of a fibroid tumor of the uterus. She had passed the menopause five years previously, but the tumor had gradually increased in size, at the time of examination reaching to the level of the umbilicus. There was a small amount of fluid in the abdomen, on opening which probably a quart of clear, straw-colored fluid ran out. The peritoneum and intestines were studded with innumerable small grayish deposits of the size of a millet-seed. Similar deposits thickly studded the serous covering of the tumor. The intestines were agglutinated, but were not adherent to the tumor. After removal of the tumor by supravaginal hysterectomy and ventrofixation of the stump the abdominal cavity was irrigated, and then, leaving the drainage-tube just behind the stump, the abdominal incision was closed. Recovery ensued. In a second case a diagnosis of ovarian tumor had been made, and examination revealed an encysted accumulation of fluid in the abdomen. The uterus was fixed, and an immovable mass was outlined in the pelvis upon the right side, which was believed to be a small ovarian tumor surrounded by inflammatory exudate. An exploratory incision was made, and three gallons of dark fluid evacuated from the abdominal cavity. A small tumor was felt in the pelvic cavity. The incision was enlarged, the tumor nucleated, and the pedicle tied off, together with the Fallopian tube. The left tube and ovary were likewise extirpated. On exposing the abdominal and pelvic cavities to view, it was seen that the viscera were thickly studded with grayish deposits. Microscopic examination demonstrated the presence of tubercle-bacilli. The patient was in good health eleven months after the operation. Two of the five cases reported terminated fatally.

DR. GILLIAM expressed the belief that when the ovaries and tubes are tuberculous it is better to remove the uterus too.

DR. J. FRANK, of Chicago, asked whether any of the members, who had operated for tuberculosis of the peritoneum, had noticed a recurrence, or how long the patient was immune from further attack.

DR. HUMISTON, of Cleveland, reported two cases upon which he had operated successfully.

DR. R. S. SUTTON, of Pittsburg, reported that he had seen a good many cases of tuberculous peritonitis, upon several of which he had operated successfully. Until within a year he had been in the habit of washing out the cavity with hot water, but now he pays no attention to this, simply opening the abdomen and cleaning out everything. He is convinced that while hot water does no harm, it does no good, in that it has no influence upon the disease. He believes in removing, as far as possible, all diseased organs.

DR. HENRY O. MARCY, of Boston, stated that he had operated in 1887 for the first time on a case of tuberculous peritonitis, the patient making an easy recovery.

He had operated several times since then for the same condition with excellent results.

DR. A. H. CORDIER, of Kansas City, called attention to the fact that Mr. Wells, as early as 1862, operated for tuberculous peritonitis, simply incising the abdomen and draining, thus curing his cases. He thinks that drainage is the principal factor that brings about a cure in this disease, but how is not definitely settled. He said the theory had been advanced that it is due to the admission of saprophytes into the peritoneal cavity.

DR. BAYARD HOLMES, of Chicago, related an interesting case of adhesive peritonitis cured by operation.

DR. DUNNING, in closing, said that Linder's observations were the most complete of any, and he found very little tendency to recurrence of the disease when it was primary and of the adhesive form; but when the disease was secondary and of the adhesive form there was a strong tendency to recurrence. His own experience had not been sufficiently extensive to furnish reliable data in this regard.

DR. BAYARD HOLMES, of Chicago, read a paper entitled

HYSTERECTOMY FOR PUERPERAL SEPSIS. WHEN SHALL IT BE PERFORMED? WITH A REPORT OF FOUR CASES.

The paper included (1) a report of four cases of puerperal sepsis treated by four different methods. (2) The pathology of puerperal sepsis in various stages. (3) Curettement in the hands of its advocates. (4) Puerperal sepsis as a cause of death in Chicago, New York, Brooklyn, and in the Charité Hospital at Berlin, with an abstract of 79 deaths from puerperal sepsis in 6635 cases.

The first case was in a multipara, twenty-six years of age, of Irish extraction, having a history of tuberculosis of the lungs, who was confined under unfavorable circumstances, with retained placenta, post-partum hemorrhage, delivery without an anesthetic with the hand of a physician, arrest of hemorrhage, gradual sepsis, failure of curettement, and death seven weeks after confinement.

The second case occurred in a woman, thirty years of age, who had had a normal confinement, with sepsis of a mild character appearing upon the fourth day, and gradually increasing until six weeks after delivery. The temperature was high, the pulse rapid, and symptoms of peritonitis with obstruction of the bowels developed. Celiotomy was performed, the right broad ligament, tube, and ovary removed, and drainage through the vagina provided for. Death occurred after eight days, without peritonitis, from phlebitis and pulmonary embolism.

The third case was in a multipara with a history of gonorrhea; an abortion followed pelvic inflammation, with peritonitis and obstruction three weeks after delivery. Both tubes were removed and abdominal drainage provided for. Death took place after ten days, without peritonitis, from phlebitis and pulmonary embolism.

The fourth case occurred in a multipara, thirty-two years of age, delivered by a midwife, with a bad history of puerperal infection, and rapid onset of a mild infection, without curettement. Obstruction of the bowels resulted with vomiting six weeks after delivery, and evidences of peritoneal effusion. Celiotomy was performed and the uterus and its adnexa removed; abdominal drainage was provided for and recovery ensued. The uterus and its appendages were carefully examined microscopically. There was evidence of necrotic endometritis, suppurative metritis, suppurative endometritis, suppurative lymphangitis in both tubes, with abscess of the ovarian ligament upon the right side and adjacent peritonitis. The bloodvessels throughout the broad ligaments were occluded, indicating a progressive infective thrombosis. The uterine tissue was filled with pus-cells occupying the perivascular lymph-spaces, with occasional obliteration of large bloodvessels. A great number of *Mastzellen* were found throughout the infected tissues. It was held that the process of puerperal infection in this case was through infective thrombosis and suppurative lymphangitis, and that the removal of both tubes and drainage would have been ineffectual.

In the city of Chicago during the years from 1881 to 1894, inclusive, there were 2127 deaths from puerperal fever. In New York during six years ending May 31, 1880, there were 250,000 deaths, of which one sixth were in females; 2236 of these deaths were due to the pregnant state. Of these, 1250 were due to puerperal infection. In Brooklyn, with 112,000 deaths during the same period, 53,000 were in females, and of these 867 died in the puerperal state, 462 from puerperal sepsis.

Of 7600 cases of labor in the hands of one of the advocates of curettement, 101 were treated by repeated curettement and irrigation. Of these, 96 recovered, and 5 died.

An abstract of the histories of these five cases was presented, showing that there was every reason to believe that after curettement had failed hysterectomy would have proved efficient in saving the patients.

A series of 6635 cases of confinement occurring in the Charité Hospital in Berlin during four successive years were then analyzed. Seventy-nine deaths from all causes occurred. Of these deaths 33 resulted from puerperal sepsis. A short epitome of the history of each case showed that only three out of these 33 cases were of such a character as to give rise to the suspicion that they might not have been saved by hysterectomy.

The following conclusions were announced: (1) Puerperal sepsis has its origin in the endometrium, and usually travels by the lymph-channels or by thrombosed bloodvessels and the lymph-channels together. (2) It still causes almost one-half of the deaths that occur in the puerperal state. (3) Curetting is ineffectual in many cases of puerperal sepsis. (4) The removal of an infected broad ligament and the drainage of a pelvic abscess or peritonitis is often ineffectual. (5) Hysterectomy should be performed, therefore, in such cases of puerperal infection as do not yield to uterine curetting and irrigation. (6) Hysterectomy should be performed whenever peritonitis is present in the course of puerperal fever. (7) Hysterectomy should be performed in cases of puerperal mania in which there is a history of endometritis without uremia. (8) Hysterectomy may not be helpful in the course of diphtheric vaginitis and endometritis. (9) Hysterectomy may not be helpful in cases of rapid early infection. (10) It may not be useful in cases of septic phlebitis reaching outside the pelvis.

DR. WM. H. HUMISTON read a paper entitled

A METHOD OF PREVENTING THIRST FOLLOWING CELIOTOMY.

He recommended that the patient should have the

usual preparation for celiotomy; *i. e.*, diet, daily baths, cathartics, etc. For three days prior to operation she should drink one pint of hot water an hour before each meal and on retiring, thus drinking two quarts of water every twenty-four hours, the last pint to be taken three hours before the time set for operating. The water is to be continued on the day previous to the operation, while the patient is restricted to a limited amount of liquid nourishment and the bowels are being unloaded. In this way is restored to the system the large loss of fluid occasioned by the free catharsis, and the patient will pass through the trying ordeal of the first thirty-six hours after the operation in comparative comfort, with no thirst, a moist tongue, and an active renal function, represented by an excretion of from twenty-eight to fifty fluidounces of urine during the first twenty-four hours, catheterization being seldom necessary. This is in keeping with the full character of the pulse noted. This plan has been recently pursued in twelve cases. In eleven chloroform was administered; in one ether. The time required to complete the operation varied from ten to fifty-five minutes. Whether the case was one of sclerotic ovaries or a pus-case with universal adhesion of all the pelvic structures, the result has been uniform and highly satisfactory, thirst being allayed and excretion stimulated.

DR. MILES F. PORTER, of Fort Wayne, Ind., read a paper entitled

CELIOTOMY IN GENERAL SUPPURATIVE PERITONITIS, WITH THE REPORT OF A CASE.

He quoted Grandin, who says regarding general puerperal peritonitis: "The women die, no matter what the form of treatment employed." Dr. Baldy says: "To my knowledge there has never been reported an undoubted case of general purulent peritonitis from any cause whatever, in which an abdominal section or any other line of treatment has succeeded in saving the patient's life." That the mortality of general septic peritonitis is large all will agree, but that it is always fatal is certainly not true. Dr. Porter then reported a successful case, and closed by saying that his object in writing the paper was to assist in arousing a sentiment against the too prevalent idea that in general septic peritonitis death is inevitable, and to encourage in these cases prompt operative interference.

DR. A. H. CORDIER, of Kansas City, Mo., read a paper on

PERITONEAL IRRIGATION AND DRAINAGE,

in which he said that the latest works on abdominal and pelvic surgery contain, like the older text-books, very short and misleading articles on the indications for peritoneal irrigation and drainage, and still less explicit directions how to use these agents intelligently and correctly. This diversity of opinion leaves the inexperienced beginner in a position of perplexity and doubt as to the special course he is to pursue in his early work. The same principles hold good in draining the peritoneal cavity that are applicable to other parts of the body. No surgeon, with all the antiseptic precautions possible to be used in opening a diffuse abscess of the thigh or other part of the body, would think of such a thing as at once closing the wound hermetically, leaving many broken-down shreds of diseased tissue in the abscess-cavity. He might have irrigated the cavity thoroughly with a 1:1000 mercuric-chlorid solution, yet he would not feel it safe to close the wound until after he had made counter-openings and introduced a drainage-tube, this being as nearly ideal surgery as it is possible to obtain in these cases. Freshly boiled, distilled, or filtered water, cooled to between 102° and 110° F., should be used in irrigating.

The following deductions were presented: (1) Drainage is a life-saving process when properly used. (2) To use it is not an admission on the part of the surgeon that his work during the operation is imperfect. (3) The use of the tube alone does not produce or leave any condition that favors the development of hernia. (4) The omentum and other structures do not become entangled in the openings in the tube. (5) A small-sized flint-glass tube, with small openings and an open end, should always be selected for pelvic drainage. (6) The tube does not give rise to a fecal fistula. (7) The tube should be used when doubt exists as to the absence or presence of indications for drainage. (8) To depend upon microscopic findings as to whether a given case should or should not be drained is seemingly scientific, but it is neither necessary nor practicable. (9) Gauze drains should rarely be used and should always be supplemented by a glass drain. (10) There is no danger of infecting the patient through a tube if the attendant is properly instructed.

DR. J. HENRY CARSTENS, of Detroit, read a paper entitled

THREE CASES OF HYSTERECTOMY FOLLOWING CELIOTOMY FOR PUS-TUBES.

The following summary was presented:

1. In the light of present experience in cases of bilateral pus-tubes it seeems that a more perfect and complete operation can be performed by abdominal section, with less danger of injury to the bladder and intestines and with a lower mortality and better ultimate results.

2. In certain cases a better immediate result is obtained by vaginal hysterectomy and drainage, but these cases frequently require a second operation to remove the ovarian tissue and parts of the tube (which cannot be removed at first in many cases) before a perfect ultimate cure is established.

3. When the sympathetic and other nerves are affected the cause is not in the uterus, ovaries, or tubes alone, but in part in each. It cannot be stated which organ is at the bottom of the trouble. Sometimes it may be only one, sometimes the other, sometimes two or all three.

4. In many cases presenting marked nervous symptoms the best results are obtained only after complete removal of every particle of the generative organs—that is, uterus, tubes, and ovaries, be this accomplished at one, two, or three operations, through the vagina or by abdominal section.

DR. R. S. SUTTON, of Pittsburg, favored abdominal section for pus-tubes. He maintained first and foremost that a uterus deprived of its appendages is of no use; second, that if left it is an organ which is liable to tuberculosis, gonorrhea, syphilis, nasty discharges, adhesions, etc. When it is decided to remove the appendages, the uterus also should be taken out.

DR. GILLIAM, of Columbus, argued against the removal of the uterus with the appendages in order to

save life, the objection being that shortening of the vagina resulted.

DR. B. M. RICKETTS, of Cincinnati, believes total extirpation will be relegated to oblivion. The dangers are cystocele, hernia, increased danger of prolonging the operation, and shortening of the vagina.

DR. HENRY O. MARCY, of Boston, favored retaining the cervix when it is healthy, and pointed out the reasons why it should not be removed. It helps materially in acting as a support to the vault of the vagina.

DR. BAYARD HOLMES, of Chicago, in discussing Dr. Cordier's paper, said that drainage is a sort of vicarious redemption for poor surgery. Whenever it is impossible to make a wound clean we must drain, and sometimes we drain when the wound is clean, but we are unable to arrest the hemorrhage. He could conceive of no other indication for drainage, whether in the abdomen, the brain, or any other part of the body, than failure to meet the one great indication of wound-treatment—to keep the wound clean.

(To be continued.)

A Malpractice-suit.—A malpractice-suit recently decided in Milwaukee, Wis., is of interest in several particulars. The trouble grew out of the accidental leaving of a rubber drainage-tube in the pleural cavity. A physician, the defendant in the case, was treating a young man, aged sixteen or seventeen years, for empyema. An operation had been performed—a resection of one rib—and drainage provided for by means of two properly placed tubes; these were secured in position by two silk stitches, each stitch passing through a tube and the skin. The wound discharged freely for several days. Upon one occasion in dressing the wound, the doctor, having gathered up the soiled gauze and thrown it into the stove, noticed that one of the tubes was missing. The dressing had been removed in such a way as to lead him to think that the tube might possibly have been thrown into the stove along with the soiled dressings. Examination with probes and forceps failed to locate the tube in the empyemic cavity. The gauze was burning or burned, and it was difficult to decide positively where the missing tube was. Another complicating circumstance was the fact that on the day previous to this the dressing had been changed by the mother of the patient and in the absence of the doctor. Under these circumstances it was not deemed best to enlarge the wound or make other incisions to look for a tube that might have been thrown into the fire or otherwise lost outside of the boy's chest. The wound healed in about the usual time, and convalescence seemed fairly established. Some months later, however, there was a slight purulent discharge through a fistulous opening in the wound, and the boy was told that a second operation would probably be necessary.

The patient then consulted a second physician, by whom he was sent to a hospital and operated upon. Resection of three or four ribs was deemed necessary, and in the discharge thus liberated was found the missing drainage-tube. The patient recovered and suit was then brought against the first physician for $20,000, claiming damages for long illness and permanent deformity.

The case was tried three times. In the first trial the jury did not agree; in the second the plaintiff was given a verdict for $2000; in the third the judge threw the case out on the ground that the plaintiff had not shown in the trial that his illness and disability were due to lack of reasonable skill and care on the part of his first physician.

This final outcome of the case, although not precluding the possibility of further litigation, meets with the very general approval of the local profession.

Cholera in Japan.—From the "Abstract of Sanitary Reports" of September 6, 1895, we learn that cholera has been rather prevalent in Japan and Korea. From July 20th to August 2d, in the district of Hiogo, 269 cases are reported, with 212 deaths; from July 1st to 18th, in the district of Osaka, 805 cases, with 730 deaths. Up to July 19th of this year 7901 cases have occurred, with 4804 deaths. The last epidemic in Japan happened in 1890, and lasted until 1892; in the two years over 42,000 deaths occurred from cholera.

A table, prepared by one of the secretaries of a provincial governor, shows that cholera first appeared in Japan in about the year 1822, again in 1858, and in 1877 and 1879 severe epidemics occurred; every three or four years since then the disease has assumed an epidemic character, the worst year being that of 1886, when 108,409 deaths were attributed to this cause.

In every year since 1877, even when no epidemic prevailed, a considerable number of cases have occurred, so that Japan can be said to be a cholera-center—though, of course, to a less limited extent than is India. It is interesting to note that in Japan the bodies of persons dying of cholera are cremated

Subscriptions to the Index Medicus.—The Philadelphia County Medical Society has subscribed $50 for two copies of the *Index Medicus;* and the Philadelphia Pathological Society $25 for one copy.

We are informed that the subscription credited in THE NEWS of August to the Quincy Public Library is in reality that of the Adams County Medical Society, of Quincy, Ill., its copy being placed in the public library for safekeeping and for the convenience of the local profession.

ON SOME CONDITIONS AFFECTING THE BEHAVIOR OF THE TYPHOID-BACILLUS IN WATER.

I.

BY EDWIN O. JORDAN, PH.D.,

ASSISTANT PROFESSOR IN THE UNIVERSITY OF CHICAGO.

IT is now generally admitted that drinking-water is sometimes, perhaps usually, the vehicle of infection in typhoid fever. The exact conditions that befriend or antagonize the specific germ in water are therefore a matter of considerable importance, and have been made the object of study by many investigators. These studies, however, have led in many cases to results so conflicting, and have been based in general on methods and material so diverse, that the chief outcome has been confusion. A valuable summary of many of the most important experimental studies upon the vitality of the typhoid-bacillus in water is given by P. F. Frankland in the first report to the Water Research Committee of the Royal Society.[1] The existence of this tabulated statement obviates the necessity of any extended account of the literature, and I shall here refer only to those papers bearing more or less directly upon the points I wish to consider.

It is essential at the outset to emphasize the necessity of a thoroughgoing examination of the specific germ used in all experiments of this kind. I have elsewhere indicated[2] the special difficulties that environ the identification of the typhoid-fever bacillus, difficulties that make it imperative to record the source, age, and character of the culture used. Additional reasons for rigorous precaution in this particular will appear presently.

The culture of the typhoid-bacillus of which I have made use was obtained on November 26, 1893, from the fresh spleen of an individual who had died of a typical attack of typhoid fever. The bacillus was obtained in pure culture from different parts of the spleen. Parallel studies of this bacillus and of a culture of the *B. coli communis* freshly isolated from normal feces, together with several "varieties" of the colon-bacillus, gave assurance that the typical typhoid-organism had been isolated. Microscopic examination showed a short, stout bacillus, with rounded ends and exhibiting active movement. It did not stain by Gram's method. Flagella were found distributed over the body of the cell, but the considerable variation in their number and size made it impossible for me to detect any fundamental difference from the flagella borne by the colon-bacillus. On gelatin plates the characteristic iridescent, irregularly notched expansion was produced; upon potato a moist, almost invisible pellicle was formed; milk was rendered slightly acid, but was not coagulated even after prolonged growth; in ordinary peptone-broth an abundant multiplication occurred, but there was no formation of indol; in peptone-broth to which formalin had been added (1:7000)[1] growth was inhibited. *No gas was produced in glucose-agar or in glucose-peptone-bouillon.*[2] On these grounds I was able to consider the organism I had isolated as the true typhoid-bacillus.

Methods. Before proceeding to compare the behavior of this organism with that of the colon-bacillus I must describe somewhat in detail my method of inoculation. It is necessary to dwell upon the manner in which the bacilli are introduced into the water, as there has been the greatest lack of uniformity in this respect, and as the importation of organic matter from the culture-media along with the bacilli has undoubtedly proved a fruitful source of error. Neglect of proper methods in this particular seriously vitiates, for example, the work of Meade Bolton,[3] De Giaxa,[4] Heraeus,[5] Straus and Dubarry,[6] Wolffhügel and Riedel,[7] and others.

The method of inoculation in my own experiments has been as follows: The typhoid-bacillus was always transferred (unless otherwise stated) from a 24-to-48-hour-old agar tube-culture grown at 37.5° C. Two or three needle-loops were re-

[2] The gas-test applied by Frankland ("The Behavior of the Typhoid-Bacillus and of the Bacillus Coli Communis in Potable Water," Proc. Roy. Soc., vol. 56), does not appear to me wholly satisfactory, owing to the fact pointed out by Smith ("The Fermentation-Tube," Wilder Quarter-Century Book, 1893) that all samples of beef-broth do not contain glucose. The use of ordinary melted gelatin-peptone, which Frankland recommends, could not always be relied upon for distinguishing between the typhoid-bacillus and the B. coli communis.

moved from the slanting surface of the agar-culture, great care being taken to carry as little as possible of the nutrient substratum along with the bacilli. A young culture is, in this respect, to be preferred to one that has grown for a longer time, as fewer dead bacilli are transferred along with the living ones. These loopfuls of bacilli were introduced into 50 c.cm. of sterile distilled water in a small Erlenmeyer flask, and the flask was shaken for several minutes in order to bring about thorough separation of the individual germs. One cubic centimeter of this inoculation-water was then added to a liter-flask containing the water in which it was desired to test the vitality. In order to determine how far this procedure introduces a quantity of nutrient substance sufficient to affect the longevity of the bacilli the following experiment was carried out: Three flasks, each containing exactly 1000 c.cm. of water drawn from the laboratory-tap, were sterilized in the steam-bath in the usual manner. To Flask A was added 1 c.cm. of inoculation-water prepared in the manner described and containing 3900 typhoid-bacilli. To Flask B were added 2 c.cm. of the same inoculation-water. To Flask C was added 1 c.cm. of inoculation-water; this flask was then sterilized by heat, cooled in running water as quickly as possible, and inoculated with 1 c.cm. precisely as Flask A.

	Flask A. (1 c.c.m.)	Flask B. (2 c.cm.)	Flask C. (1 c.cm.) Sterilized inoculation-water + 1 c.cm.
Immediately after inoculation.	9000	18,000	9000
After 1 day	8415	17,325	9405
" 4 days	7390	12,870	8910
" 7 "	5775	9,936	6930
" 11 "	3905	7,260	3465
" 17 "	3025	7,205	2530
" 26 "	1485	2,805	1705
" 33 "	935	1,210	825
" 40 "	825	930	1045
" 48 "	200	84	142
" 62 "	81	9	2
" 83 "	5	5	0
" 103 "	0	0	0

A similar experiment gave a confirmatory result:

	Flask A'. (1 c.cm.)	Flask B'. (2 c cm.)	Flask C.' (1 c.cm.) Sterilized inoculation-water + 1 c.cm.
Immediately after inoculation	3900	8000	3900
After 4 days	1870	3190	1815
" 20 "	58	113	42
" 41 "	6	4	9
" 55 "	2	0	3
" 75 "	0	0	0

These experiments show that the amount of food-material introduced by the method of inoculation that I have employed is not large enough to affect perceptibly the longevity of the bacilli.
